ADENOMATOID TUMOR: REPORT OF TWO CASES AND SOME CONSIDERATIONS

Yasunori Kubo and Shohei Murata

From the Department of Urology, Kyoto Prefectural University of Medicine

Among the tumors arising from the testicular appendage, a benign tumor which is classified under the name of “adenomatoid tumor” is present. This benign tumor is characteristically different from ordinary benign and malignant tumors.

Concerning the mother tissue from which this adenomatoid tumor arises, many theories have been advocated on the endothelial, epithelial and mesothelial origin but no one theory has been universally accepted. This appears to be the reason why Golden-Ash adopted such a vague descriptive term as “adenomatoid tumor”.

In Japan, Harada was the first to use the name “adenomatoid tumor” in 1950 and 16 cases have been reported so far. With the addition of three cases reported by Sakaguchi, Nakamura, and Noma, probably representing the same disease, a total of 19 cases is obtained.

We have recently experienced 2 cases of this disease and conducted histological and histochemical studies. The results of these studies with a review of the literature are reported in this paper.

CASES

Case 1

Patient: K. M. 36-year-old male.
Initial examination: September 15, 1964.
Chief complaint: Tumor in the left scrotum and dull pain in the testicular area.

Family history: Non-contributory.

Previous history: At the age 24 years, the patient had pulmonary tuberculosis.

The patient has no children after 10 years marriage.

History of the present illness: For approximately past one year, a small-finger tip sized painless tumor was palpated in the upper pole of the left testicle. The patient then complained of dull pain in the left lower abdomen and testicular area. He had received no particular treatment on these complaints. While he was admitted to the department of internal medicine because of acute hepatitis, he was thereby referred to the department of urology.

Local findings: The right testicule, epididymis, and vas deferens were all normal. No abnormality was noted in the left testicle. A small-finger tip sized, spherical, elastic firm tumor was palpated to be tightly attached to the head of epididymis. No tenderness was encountered.

From the above clinical findings, a diagnosis of left chronic epididymitis was made and a left epididymectomy was carried out since tuberculosis was suspected.

Operative findings: About 1/4 of the lower surface of the tumor was attached to the head of the epididymis and adjacent to the visceral surface of the tunica vaginalis, while a larger part of the remaining por-
tion appeared to be buried in the spermatic cord (Fig. 1). Although the attachment of the tumor to the epididymis was rather tight, that to the spermatic cord was rather loose and readily separated. The tumor was therefore removed along with epididymis.

Gross findings: The resected tumor measured approximately 8 mm in its diameter and the shape was spherical. The tumor was elastic firm, appearing yellowish white in color, while the cut surface was smooth and gray-white, giving the appearance of a fibroma. The tumor was covered by a fibrous capsule and was easily distinguishable from the epididymis (Fig. 2, 3).

Histological findings: Large light-colored cells resembling epithelial cells gave a gland-like appearance forming many glandular lumens (Fig. 4, 5). There were also cells with vacuoles scattered within the cytoplasm. A relatively abundant fibrous interstitial was present.

Histological findings: Pap, Sudan, mucicarmine, and PAS stains, and glycogen and acid mucopolysaccharide were studied. In the Pap stain, the reticular fibers were relatively coarse (Fig. 6). Staining for fat was negative in the Sudan stain. Bestcarmine staining revealed negative mucin. PAS was negative except in the interstitium and part of the vacuoles. No glycogen was noted. Alcian blue staining demonstrated the presence of acid mucopolysaccharide as β-metachromasia in the vacuoles at various sites and in the glandular lumen (Fig. 7).

Case 2
Patient: S. K. 31-year-old male.
Chief complaint: Dull pain in the right scrotal area.
Family history: Non-contributory. One child.
Previous history: At the age of 16, the patient had pleurisy. Two years ago an appendectomy was performed.
History of the present illness: For 2 to 3 days the patient had pain in the right testicular area and also dull pain in the lumbar region. His home doctor examined him and referred him to us under the suspicion of epididymitis.
Local findings: The left testicle, epididymis, and deferent duct were all normal. No abnormality was noted in the right testicle. At the head of the right epididymis, a small-finger tip sized spherical firm tumor was palpable with marked tenderness.
Based on these clinical findings, a right epididymectomy was performed under the suspicion of right tuberculous epididymitis.
Operative findings: No abnormality was seen in the right testicle and tunica vaginalis. At the head of left epididymis a spherical and small-finger tip sized induration was noted (Fig. 1). The epididymis was completely free of adhesions to the surrounding tissues and dissection was readily accomplished. Resection was carried out including the healthy body and tail of the epididymis.
Gross findings: The resected tumor was

almost spherical with a diameter of approximately 10 mm. The consistency resembled that of cartilage, the color was yellowish white, and the cut surface was smooth and gray-white with a slightly yellow-brown central portion. The general appearance resembled a fibroma, covered by a fibrous capsule and was distinguishable from the epididymal tissue (Fig. 8, 9).

Such macroscopic findings gave rise to the suspicion of the so-called "adenomatoid tumor", so that histological and histochemical studies were conducted.

Histological findings: The tumor consisted of a collection of rather light epithelium-like cells giving a cord-like or small honeycomb-like appearance. Vacuole formation was noted in cells at various sites but no adenomatous structure was present (Fig. 10, 11, 12). Although the stroma was scanty, the tumor was definitely distinguishable from the epididymal tissue because of the fibrous capsule. While the epididymal tissue was normal, in the area between the tumor and the testicle an increased amount of the stroma was noted. The tubular lumen was atrophied. On the visceral surface of the tunica vaginalis, a marked thickening of the fibrous capsule was noted. Part of this thickened area contained tumor tissue.

Histochemical findings: A Pap stain revealed rather poor reticular fiber formation and the PAS stain was mildly positive in the interstitium. Some of the vacuoles contained positive PAS material. This material appeared to be β-metachromasia in the alcian blue stain, probably representing acid mucopolysaccharide (Fig. 13). Mucin, glycogen and fat stains were negative.

**DISCUSSION**

Adenomatoid tumor of the testicular appendage has been considered to be a considerably rare disease until recently. In Japan, before Harada's report, only 3 cases were reported; namely adenomyoma by Sakaguchi, and lymphangioma by Nakamura and Noma.

However, after two additional reports by Minami, many cases have been reported. By 1967, more than 20 cases were reported as shown in Table 1. This is probably not due to a sudden increase of this disease, but rather due to an increased interest in this disease.

The speed of development of this disease is rather slow and most of the patients are free of subjective complaints. No malignancy has been associated with this tumor. The age of the most frequent occurrence is between 20-40 years, and patients at this age are rather preoccupied with their livelihood. Due to these reasons, the tumor is usually detected incidentally. Even if a tumor is found, it is frequently left untreated as chronic or tuberculous epididymitis, or post-inflammatory induration. Even upon extirpation, histological examination is frequently neglected so that the tumor escapes proper attention and identification.

According to the report of Imamura, collecting and classifying 55 cases of epididymal tumors in Japan, 17 of 33 benign tumors were adenomatoid tumor. According to the series of 134 cases collected by Longo et al, 53% of all epididymal tumors was adenomatoid tumors. The position that this disease holds among epididymal tumors thus appears to be rather important. As mentioned above, the most frequent occurrence is seen between 20-40 years of age. In the report of Burros et al an adenom-

(* Nonaka's case is not “adenomatoid tumor”)

Adenomatoid tumor in a newborn is included. The disease in Japan ranged in age between 18 and 73 years, but 12 cases which represent the majority of the cases fall in the fourth decade.

Lee et al. found 58% of the tumors on the right and 42% on the left, while Jackson found 56% on the right and 44% on the left, suggesting a slight right sided preponderance. The cases in Japan occurred on the right in 10 and on the left in 12, suggesting a slight left preponderance.

Although this tumor has generally been reported as a tumor of the epididymis, determination of the site of occurrence is rather difficult since the mother tissue of this tumor is involved. Consequently, it is almost impossible to describe any one case as typical. The sites of occurrence described in the literature are as follows. According to Jackson, the tail portion of the epididymis is frequently affected. However, in 20 cases we collected from the literature and two cases of our own experience (one case was excluded due to insufficient description) 7 were found in the...
portion of epididymis, from the head to the corpus in 2, and the tail portion in 11. No special preponderance of occurrence in the tail portion was detected. In another case reported by Nonaka⁴⁰, the lower pole of the testicle was affected, although it was described by the name “benign mesothelioma”.

The tumor is generally small and the majority were smaller than the small-finger tip. According to Campbell⁶, 2 to 5 cm is the ordinary size, whereas in Japan, Endo¹⁰ reported a case in which the goose egg-size tumor was smooth and firm, being clearly demarkated by a capsule from the surrounding tissue. One case of Sakatoku & Takahashi⁴⁶ had a direct communication with the epididymis, according to histological finding.

The histological findings are characterized by gland-like structure consisting of endothelial or mesothelial elements. Cells contain vacuoles of various size. Occasionally, these cells are arranged in a cord-like and sometimes a gland-like fashion, with various transitional types between. Although the interstitial tissue is said to be relatively abundant, collagen fibers and elastic fibers are rather scanty. This tumor has been classified histologically into 3 to 4 types. Sakatoku⁴⁶ classified 4 types, from a solid cell cord type to an angiomatous type as shown in Table 2. Prior to this, Golden-Ash¹⁵ and Lee et al.²⁸ independently classified it into 3 types (Table 2). The cases of our experience in the present report were classified according to these standards. The first case probably represents the transitional type between type 2 and 3 according to Golden-Ash, or type 3, tubular type according to Lee et al. and Sakatoku. Case 2 probably belongs to the intermediate type between type 1 and 2 according to Golden-Ash and Lee et al., and type 2 or the cell cord type with slight vacuolation according to Sakatoku.

Histochemical studies have long been conducted on the contents of the vacuoles. Sudan and mucicarmine staining have all been negative. Glycogen was negative. However, PAS positive vacuoles have been said to be present. According to Stavrides⁵⁰ this substance is acid mucopolysaccharide in view of the β-metachromasia by alcian blue.

Concerning the mother tissue of the adenomatous tumor, Leighton²⁹ proposed an endothelial origin and Naegeli⁴² did an Wolffian duct origin both in 1912. Various theories have thereafter been advocated. However, classification would give four theories of origin, as shown in Table 3.

Some adhere to the theory of Leighton et al based on the finding simulating lymphangioma, but few have supported this theory in recent years.

According to Naegeli and some authors, this disease is not a neoplasma since no blood or lymphatic elements are present in

Ringano, Marcandier, Nicod, Scalfi: cited by Jackson 42
Naegeli: cited by Rankin 46

Evans et al 41 on the other hand, pointed out the intimate relationship between the origin of this disease and the serosal surface of the tunica vaginalis, suggesting the possibility of mesothelial cell origin. He therefore gave the disease the name of mesothelioma. However, Golden & Ash 51 opposed this theory and pointed out a considerable histological difference between this tumor and mesothelioma of other part of the body. While, in recent years, Stavrides 50 has strongly supported the mesothelial origin theory in view of the histological demonstration of hyaluronic acid which is probably formed by the mesothelial cells in the vacuoles and the ability of mesotheliomas to differentiate into fibroblast or mesonephric structures.

In most of reports from Japan, the papers cite from the literature on pathogenesis of
this disease, but few discuss it based on their own experience. Only Sakatoku & Takahashi\(^6\) has proposed the theory of mesonephric origin from embryological standpoint of the tissue as they found a direct connection of the tumor with epididymal tissue in one case.

Nonaka\(^6\) reported a case of so-called “benign mesothelioma” in which the origin was probably the tunica alba. Tsuchida\(^12\) pointed out the epithelial structures and the absence of any relationship with the serosa, suggesting the possibility of Müllerian duct origin (Table 3).

Two of our own cases must be then discussed. All part of both tumors appeared to be of epididymal tissue origin and was clearly distinguishable from the epididymis both macroscopically and histologically, so that it is rather difficult to state that the origin was the ductuli efferentes. Especially in the 2nd case, the epididymal tissue adjacent to the tumor tended to undergo atrophy due to compression. However, any relationship with the serosa such as the tunica vaginalis was not clearly demonstrable. Histochemically, mucopolysaccharide probably representing hyaluronic acid as pointed out by Burnting\(^4\) was found in the vacuoles in addition to positive PAS stain and glycogen content in agreement with the theory of Stavrides\(^50\). In view of the above findings, the mesothelial origin according to Evans\(^11\) and Stavrides appears to be probable. However, many questions still remain as to whether this may be identified as a “benign mesothelioma”. Recently, Takahashi et al\(^66\) gave the diagnosis of benign mesothelioma to a tumor with multiple points of origin on the tunica vaginalis. According to this author, histological finding of this tumor is entirely different from the so-called adenomatoid tumor.

From the histochemical findings of our own cases which we think important, evidence affirming the mesothelial origin theory was obtained. However, we do not insist on the theory that the tumor occurs from the serosa. Mesothelial origin presenting as a hamartoma appears to be most probable. In view of the opinion of Stavrides\(^50\) that “mesothelium has the ability to differentiate into mesonephric structures”, the hamartoma theory of Naegeli\(^42\) might be understood without limiting the mother tissue to the mesonephros. From such a viewpoint, as Golden & Ash\(^19\) pointed out, it would be quite possible that an adenomatoid tumor presents histological findings entirely different from those of mesotheliomas occurring in other site. The absence of universal opinion on the origin of this disease might be due to the fact that “adenomatoid tumor” and “benign mesothelioma” have been treated as if they were the same disease. In order to clear such confusion, we consider that a “benign mesothelioma” developing in the tunica vaginalis is different from an adenomatoid tumor. We then suppose the presence of two types among the adenomatoid tumors, that is, some developed from the mesonephric tissue of the epididymis and lacked mesothelial characteristics with frequent continuity with the epididymal tissue, while others retained strong mesothelial characteristics without any continuity to the epididymal tissue and developed from the mesothelium or mesonephric tissue through differentiation.

**SUMMARY**

“Adenomatoid tumor, appearing on the head of the left epididymis of a 36-year-old male and on the head of the right epididymis of a 31-year-old male were reported. In both of them histologically found were
tubular type structure and cell cord with slight vacuolation. Both cases showed positive acid mucopolysaccharide, probably representing hyaluronic acid, in the vacuoles and the tubular lumens. The possibility that the disease has a mesothelial origin was thus histochemically demonstrated.

However, in view of the difference between adenomatoid tumors reported in the literature and mesotheliomas occurring in other sites, a relationship with the Wolffian duct cannot be completely denied. Anyway, this should be considered an entirely different disease from the so-called “testicular benign mesothelioma”. Among various cases of this disease, subtypes with different pathogenesis might be present.

睾丸附属器より発生する腫瘍には、支持組織より発生する通常の良、悪性腫瘍のほか、 “adenomatoid tumor” の名のもとに総括される良性腫瘍の存在が知られている。

そしてこの腫瘍の発生母地については、古くから種々の説がとなえられてきたが、普通的かつ確実な説がないまま今日に至っている。

本邦では原田（1950）が最初に adenomatoid tumor の名を用いて報告し、それ以前の同様例をみられる坂口（1917）、中村（1942）、野間（1949）などの例を加えて今日まで計19例に達する。

われわれは最近本症の 2 例（Case 1：36才、左副睾丸頭部；Case 2：31才、右副睾丸頭部）を経験し、組織ながらに組織化学的検索を行なう機会を得たので、その成績を述べるとともに若干の文献的考察を行なった。

自験 2 例は組織学的に tubular type および cell cord with slight vacuolation とみられ、いずれも空胞内ないしは管腔構造のなかに hyaluronic acid と思われる acid mucopoly-saccharide を有していた。

組織化学的所見を重視する Stavrides もの説に従えば、これら 2 例はいずれも mesothelium origin の可能性を裏づけるものであるが、文献にみられる個々の例、または他の部の mesothelioma との相違点などを考慮するとWolffian duct との関連を全く否定することも困難となる。いずれにせよ、いわゆる “testicular benign mesothelioma” とは別の疾患と考えるべきであろうし、本腫瘍のなかにもその発生経路を異にする二、三の変型が存在するのではなかったかと推論した。
