(Received 6 August 2012; accepted 18 September 2012; published online 11 October 2012)

We have prepared a three-dimensional magnetophotonic crystal and observed modulated Faraday rotation around its photonic band gap. The magnetophotonic crystal was prepared by the self-assembly of highly monodispersed silica spheres, which were heavily impregnated with maghemite (γ -Fe₂O₃) nanoparticles. The slab sample with a thickness of 10 μ m shows a clear photonic band gap centered at $\lambda = 620$ nm in optical transmittance. Faraday rotation is notably modified inside the photonic band gap. © 2012 American Institute of Physics. [<http://dx.doi.org/10.1063/1.4757608>]

A photonic crystal (PC) is a periodic array of macroscopic dielectric materials of different refractive index on the scale of the optical wavelength. The presence of photonic band gap (PBG), in which the propagation of electromagnetic waves is forbidden, is a well-known feature of PCs.¹ This provides a mechanism to control and manipulate the flow of photons.

Constructing a PC from a magnetic material or filling a PC with a magnetic material can result in the formation of magnetophotonic crystals (MPCs).² Such materials would give an extra degree of freedom to achieve enhanced nonreciprocal optical phenomena such as magneto-optical Faraday and Kerr effects. Indeed, it has been demonstrated that the magneto-optical response of one- (1D)^{3–8} and two-dimensional (2D) MPCs is significantly enhanced at band edge frequencies. This remarkable result has prompted the investigation of three-dimensional (3D) MPCs in which the periodicity in the three directions could lead to a complete PBG in the optical regions.

Although achieving high-quality 3D MPCs is much more complex and still a challenge, there are several works producing a 3D MPC by using a self-assembly technique.^{9–15} The general process involves the self-assembly of monodispersed spheres into an fcc lattice, followed by an infiltration of magnetic materials in its interstices. A simple example is filling the interstices with a magnetic liquid,¹⁰ although in this case the MPC is not all-solid. In order to make all-solid 3D MPCs, Pavlov *et al.* infiltrated magnetite (Fe₃O₄) nanoparticles into the self-assembled silica spheres.¹¹ Recently, Caicedo *et al.* made a 3D inverse opal MPC consisting of Ni nanoparticles and alumina by using polystyrene colloids as a sacrifice template.¹² A general drawback of this approach, i.e., self-assembly and infiltration, is that although the self-assembled opal is highly ordered and periodic, the infiltration with magnetic nanoparticles inevitably disturbs the opal structure, making the PBG broader and less clear. This smears the effects the PBG on magneto-optical response of MPC. Actually, only a limited number

of 3D MPCs exhibit magneto-optical effects modified by PBG.^{10–12}

In this study, we present a building block by which an MPC can be built without being suffered from infiltration: Our MPC is constructed of highly monodispersed silica spheres inside which magnetic fine particles are heavily impregnated. Because they are inside the silica sphere, the presence of magnetic components does not directly disturb the self-assembly process. Here, our slab sample shows a clear dip due to PBG in the optical transmittance. The measurement of Faraday effect shows the modification of the rotation angle near the PBG.

The samples were prepared as follows:¹⁶ First, the monodispersed mesoporous silica sphere, MMSS, which possesses highly periodic mesopores, was prepared via a surfactant-templated sol-gel route.^{17,18} Then, ferrocenecarbaldehyde as an iron source was infiltrated in the mesopores and the silica spheres were heat treated at 1273 K. During the heat treatment, maghemite (γ -Fe₂O₃) nanoparticles were precipitated and grown to the size ~ 3.1 nm, while the mesopores were collapsed. The final spheres had an average diameter of 263 nm and contained as high as 21.2 wt. % γ -Fe₂O₃ measured by energy-dispersive x-ray spectroscopy (EDX). This amount is considerably higher than that used in the work by Fang *et al.*, where Fe₃O₄ nanoparticles were loaded on silica spheres up to 6.4 wt. %.¹⁵ Magnetic measurement proved that the spheres impregnated with γ -Fe₂O₃ shows superparamagnetism at room temperature.¹⁶ Finally, by following the procedure described in Ref. 19, the γ -Fe₂O₃-impregnated spheres were assembled into a 3D MPC in between two slide glasses. In short, an aqueous dispersion of the γ -Fe₂O₃-impregnated spheres was injected into a fluidic cell, comprising two glass substrates (length: 38 mm, width: 26 mm, thickness: 0.7 mm) and two spacers (thickness: 10 μ m) sandwiched between them. The evaporation of water under ambient conditions resulted in the formation of an fcc opal with the (111) plane oriented parallel to the slide glass surface. A reference silica sample was also prepared following the same procedure by using the same MMSS heated at 1273 K but without an iron source inside. The resultant samples were dried *in vacuo* at 423 K prior to

the measurements. The distance between adjacent layers in the [111] direction is $\sqrt{2/3} \times D = 215$ nm, where D is the diameter of the sphere, so that the crystal with $10 \mu\text{m}$ thick consists of ~ 50 layers.

The optical images of the sample are shown in Figs. 1(a) and 1(b), indicating that the sample has both glossy and matte domains. Scanning electron microscopic (SEM) images in Figs. 1(c) and 1(d) confirm that this comes from the difference in the spatial arrangement of spheres; the sample consists of ordered and disordered domains. It is also confirmed that no $\gamma - \text{Fe}_2\text{O}_3$ particle appears on the surface of silica spheres.

The optical transmittance was measured by using a spectrophotometer (JASCO, V-570). The Faraday rotation angles were measured at room temperature by the polarization modulation technique using a commercial measurement system (JASCO, Model K-250) with an Xe lamp as a light source. The measurements were also done for the pair of slide glasses in order to subtract the contribution of diamagnetic slide glasses sustaining the sample.

A problem in evaluating the magneto-optical response of opal-based MPCs is an optical activity that stems from their structures, which has been pointed out recently.^{12,14,20} Anisotropy appears both intrinsically due to the symmetry in opal structure and extrinsically due to internal strains during the fabrication. The anisotropy causes optical birefringence and dichroism, which overlap the magneto-optical response in the measurement. In order to separate those effects, we obtained the Faraday rotation data by subtracting the rotation data measured exactly at the same spot but without applying an external magnetic field from the raw data.

(b) Optical microscopic image of the sample, showing the interface between the ordered and disordered domains. (c) SEM image of the disordered domain of the sample. (d) SEM image of the ordered domain of the sample.

Figure 2(a) shows the optical transmittance (T) of the sample, on both the ordered (denoted by a solid curve) and disordered (a dotted curve) domains. The data for the

FIG. 2. (a) Optical transmittance of the disordered (a dotted curve) and ordered (a solid curve) domain of the sample. (b) and (c) Faraday rotation of the disordered (b) and ordered (c) domain of the sample. Curves are the guides for the eyes. The black and gray data denote the rotation with the external magnetic field of +15 and -15 kOe, respectively. The data were plotted after subtracting the diamagnetic contribution from a pair of slide glasses sustaining the sample, and also the response of the sample without applying the magnetic field. (d) The difference between the Faraday rotation angle of the ordered domain and that of the disordered domain under the magnetic field of +15 kOe (black) and -15 kOe (gray). (e) Faraday rotation of the reference silica sample consisting of the same silica spheres but without $\gamma - \text{Fe}_2\text{O}_3$ inside: black (+15 kOe), gray (-15 kOe). The data were plotted after subtracting the diamagnetic contribution from a pair of slide glasses and the response of the reference sample under 0 kOe. The inset shows the optical transmittance of the reference sample.

disordered domain show an absorption below 600 nm, which comes from both an absorption of $\gamma - \text{Fe}_2\text{O}_3$ ^{21–23} and multiple light scattering by the spheres. While little difference is seen at longer wavelengths (typically $\lambda \geq 700$ nm), T of the ordered domain shows a dip at around $\lambda = 620$ nm, which corresponds to its PBG. It is also noticed that T is larger for the ordered domain at the shorter wavelength edge of the PBG ($\lambda \leq 580$ nm).

Figures 2(b) and 2(c) show the Faraday rotation angle as a function of wavelength for the disordered and ordered domain, respectively. Here, the data taken without an external magnetic field, and the diamagnetic contribution from the pair of slide glasses, were subtracted from the raw data. The black and gray curves refer to the data taken by applying +15 and –15 kOe, respectively. As shown in Figs. 2(b) and 2(c), these two curves are symmetric with respect to the x axis (the wavelength axis), due to the nonreciprocal nature of the Faraday effect. This also indicates that the influence of structural optical activity, which is independent of the external magnetic field, was properly subtracted. The rotation observed in Fig. 2(b) is attributed to the superparamagnetic $\gamma - \text{Fe}_2\text{O}_3$ nanoparticles.^{21–24} The difference in refractive index (Δn) for the left- and right-handed circularly polarized light is induced through the magnetic moments of individual nanoparticles oriented parallel to the external magnetic field. As a result, the polarization plane of the incident linearly polarized light is rotated as it travels inside the sample. Unlike the disordered domain shown in Fig. 2(b), the ordered domain exhibits notable modification around $\lambda = 620$ nm [Fig. 2(c)], corresponding to that of PBG in T [Fig. 2(a)]. At this wavelength, the rotation angle is decreased in magnitude and changes its sign. This modification is better visualized in Fig. 2(d), where the Faraday rotation angle of the disordered domain was subtracted from that of the ordered one. The difference shows a maximum at $\lambda = 625$ nm, which is in the middle of the PBG.

Figure 2(e) shows the Faraday rotation of the reference silica sample without $\gamma - \text{Fe}_2\text{O}_3$ nanoparticles. The sample exhibits a PBG in its transmission [see the inset of Fig. 2(e)], but no significant rotation is observed in the Faraday effect measurements. This indicates the small contribution of the silica spheres to the Faraday effect.

Figure 3 depicts the angle of Faraday rotation as a function of external magnetic field. In Fig. 3(a), we plot the data for the disordered domain at two wavelengths, $\lambda = 560$ nm (black) and 620 nm (gray). For the both wavelengths, the Faraday rotation shows a negative slope with respect to the magnetic field and is saturated at high magnetic fields with no hysteresis, confirming that the nanoparticles are superparamagnetic at room temperature. The slope of the curve is less steep for the data at $\lambda = 620$ nm, which is in agreement with the observation in Fig. 2(b). Figure 3(b) shows the results for the ordered one. A black line indicates the data taken at $\lambda = 560$ nm, i.e., outside the PBG, showing the same behavior as the disordered domain. In contrast, at $\lambda = 620$ nm (gray), inside the PBG, the behavior is similar to that of the disordered domain at lower magnetic fields, whereas at higher magnetic fields the slope changes its sign and becomes positive. This result indicates that the effect of PBG

FIG. 3. Magnetic field dependence of the Faraday rotation for the disordered (a) and ordered (b) domain of the sample. The data were taken at 560 nm (black dots) and 620 nm (gray dots).

on the Faraday rotation is notable especially when the magnetic field is high.

The change in the Faraday rotation can be discussed in terms of the modification of effective refractive index by PBG. The presence of PBG causes an anomalous dispersion in refractive index associated with extinction by Bragg diffraction.^{25,26} Since the condition of Bragg diffraction depends on the refractive index, a non-zero Δn in PCs leads to a difference in the spectral position of PBG and thus a difference in the spectral range of anomalous dispersion for left- and right-handed circularly polarized light. Consequently, the Δn induced by the magnetic field is further modulated around the spectral area of PBG, resulting in the modified Faraday rotation as seen in Fig. 2(c). This can also explain the observation in Fig. 3(b), where the modification is notable at higher magnetic fields. Preceding works on 1D⁸ and 3D¹² MPCs highlighted the enhancement of the magneto-optical effect at the band edge due to a reduced group velocity, which is not very clear in our observation.

In summary, we have fabricated a magnetophotonic opal made of highly monodispersed silica spheres, heavily impregnated with $\gamma - \text{Fe}_2\text{O}_3$ nanoparticles. We examined its Faraday effect after subtracting the effect of optical activity that comes from its structure. The result shows that our material is one of the few 3D MPCs that exhibit a modified Faraday effect due to PBG, proving that the present technique, i.e., self-assembly of spheres heavily impregnated with magnetic nanoparticles, is effective in preparing 3D MPCs with good optical quality.
