Strobilation in Scyphozoa has been well known as a process to produce ephyrae. This process might include the basic aspect to understand the mechanism of cellular differentiation and transformation for the particular pattern of metamorphosis. We believe that the strobilation therefore seems to provide a unique opportunity for the study of growth and development, which has been pointed out by SPANGENBERG (1965). Although some known environmental factors such as the lighting condition and the low temperature could initiate the strobilation (cf. recent review, SPANGENBERG, 1968), we know little about the possible change which may occur in either the substantial or cellular level during the strobilation and the further metamorphic process. In this report, we are going to describe the morphological and physiological aspects of strobilation in *Aurelia aurita*.

## 1. Strobilation Process

*Material:* Polyps of *Aurelia aurita* used in this study have been obtained from the Department of Biology, Tokyo Metropolitan University. This material had been maintained for several years under laboratory condition using natural sea water. In our laboratory, these polyps have been kept in artificial sea water, Jamarin (manufactured by Jamarin Laboratory, Osaka, Japan) at a temperature range from 20° to 23°C for 3 years. They were fed twice a week with newly hatched *Artemia salina*. Temperature is a serious morphogenetic parameter. For instance, lowering the temperature could cause the initiation of strobilation in marine scyphistome (KAKI-NUMA, 1962; SPANGENBERG, 1968). In order to yield many strobilae of *Aurelia aurita*, the polyps which were originally derived from a single polyp by budding were transferred into the artificial sea water, Jamarin (this will be abbreviated as ASW in the following description) at 15°C and maintained until the ephyrae were liberated from the mother polyp. During the present observation, we found that the percentage of strobilation

initiation and the number of segments in strobilating polyps were markedly varied depending on both the original stage and size of the polyps. Thus, we used exclusively such polyps whose heights (from peduncle to a level just below tentacles) were distributed within 2.0–2.2 mm range when they were in relaxation state.

*Morphological Survey of Strobilation Process:* In the developmental studies, morphological details of the strobilation during the process of development can be illustrated as in Fig. 1. This process can be sub-divided into six sequential stages according to the following characteristics.

Fig. 1. Strobilation process of *Aurelia aurita*.

Stage I is the polyps which do not develop any transverse furrow. However, they will begin to elongate distoproximally within a few days, decreasing their width after the successive transfer to the ASW at a lower temperature. At this time, we usually recognized the following morphological changes: (1) the orange colored pigmentation which is commonly observed in the distal part of polyps begins to lose the original diffused distribution and start to concentrate at the proximal part, (2) the marginal region just below the tentacles starts to swell gradually and (3) the internal septa become more clear and detectable such as the surface ridge. Usually this state

Fig. 2. The average change in body height and width of strobilating polyps followed in three different groups, A, B and C. h or w means height or width, respectively. In group A, 20 polyps which had 2.5 mm height and width were employed for measurement. Fifteen polyps were examined in groups B and C. Their height and width were 2 mm in group B and 1.5 mm in group C.

increase of the body length can be seen from Stage II to Stage V, while the slight reduction of the body width occurred during the morphogenesis (Fig. 2). It is interesting to note that the increase of the body length (height) always accompanies the decrease of the width of the distal part. However, the width of the proximal part may not necessarily decrease in size, and may compensate the even volume distribution for future ephyrae, because each individual ephyra liberated from the distal part always demonstrated the same body size compared with the ephyrae derived from the proximal part. The reduction of the body length at Stage V can be explained as the result of the flattening of each matured ephyra.

## 2. Incorporation of Radioactive Precursors

To understand the physiological base of the successive strobilation, the incorporation of radioactive precursors by polyps and strobilae at different stages has been examined. The organisms were incubated in ASW, and  $^3\text{H}$ -thymidine,  $^3\text{H}$ -uridine or  $^3\text{H}$ -leucine was applied independently. The dose of two radioactive nucleotides was  $20 \mu\text{C/ml}$  and  $5 \mu\text{C/ml}$  in the  $^3\text{H}$ -leucine. Flash labelling technique (1 hr, 2 hr and 4 hr) was used in the present work. Immediately after the completion of the

flash labelling, the organisms were fixed with 10% neutral formalin at ice cold temperature, and sectioned following with the standard histological technique. Sakura MR-M<sub>2</sub> was chosen for the dipping emulsion.

Fig. 3. Autoradiographs showing the incorporation of radioactive precursors.

A: Thymidine uptake in the distal half of a polyp at stage Ia. B: Thymidine uptake in the middle segments of a strobila at stage III<sub>7</sub>. C: Uridine uptake in the proximal part of an early strobila at stage II<sub>1</sub>. D: Leucine uptake in the gastric region of a polyp at stage Ia. E: Leucine incorporation in the middle segments of a strobila at stage III<sub>7</sub>. All the autoradiographs were prepared after the 2-hrs flash labelling at a dose described in the text (p. 182).

Although hydra has been thought to be impermeable to most exogenous free compounds (BURNETT, BAIRD and DIEHL, 1962), the present results indicated that all three radioactive precursors could be incorporated into the cells. Details of this and other results obtained from pulse labelling will be published later. Pattern analysis strongly suggests that the incorporation of the radioactive material is dependent on the stage of the morphogenesis. The axial distribution of DNA, RNA and protein has been confirmed and reported in two other hydroid species (LI and LENHOFF, 1961; TARDENT, 1963). The high rate of incorporation at the distal part is found in *Aurelia*, regardless of the difference of tracer employed, even though some differences exist depending on the type of tissue. Thymidine and uridine could easily be incorporated into the ectoderm but not into the endoderm at the polyp stage. However, endoderm becomes more permeable than before, especially in the strobila (B and C in Fig. 3). The incorporation of these tracers continued until the completion of ephyra, although the rate decreased gradually.

However, leucine behaved differently. Leucine uptake is found in both the ecto- and endoderm at the polyp stage (D in Fig. 3). At the strobilation stage, ectoderm tends to show a somewhat decreased incorporation of tracer (E in Fig. 3) during the early stage of strobilation, and resume activity at a later stage. Based on the results described above, it is possible to conclude that the level of nucleic acids and protein synthesis in both ectoderm and endoderm are different and fluctuate during the process of strobilation following the built-in programme.

### 3. Mutual Relationship between Ectoderm and Endoderm in Strobilation

SPANGENBERG (1965) examined the subsequent development of the segment separated from the strobilae which already had three segment, and he reported that the distal segment could develop into ephyra. We found that the segment obtained from the strobilae at different stages, namely Stage II<sub>1</sub> and Stage II<sub>5</sub> showed subsequent development but reached a different developmental state depending on the experimental condition. For example, ephyra formation from the operated segment not only depends on the developmental stage but also the size of the segment (KATO, AOCHI and SAKAGUCHI, 1973). The endoderm holds some regulational mechanism in the process of strobilation. When the strobilae at stage II were cut transversely at the site of the first furrow, the distal part showed some difficulties to develop into ephyrae (5 out of 15 cases and 10 remained as polyp), but almost of all of the unsegmented proximal part would continue further segmentation towards the direction of ephyra formation (14 out of 15 cases, Fig. 4). From this we can consider that the developmental programme has more or less been established when the first segment appeared in the strobila. It was found, however, that if most of endoderm are removed mechanically from either the isolated segment or the non-segmented proximal part, the test piece could not continue further strobilation (A in Fig. 5 and Fig. 6). If the well

advanced strobilae (Stage II<sub>5</sub>) were used, the segmented part could develop into an ephyra, regardless of the presence or absence of endoderm. The facts seem to suggest that the endoderm may hold a regulating mechanism to lead the ectoderm to continue further strobilation and ephyra formation.

#### 4. In Vitro Culture of Dissociated Cells taken from Polyp and Strobilae at Different Stages

The *In vitro* culture of single cells had been widely carried out by many investigators for studies of tissue organization and differentiation. Using fresh water hydroids,

Fig. 5. A shows the case which lost most of the endoderm in the proximal part of the body. Specimen has been obtained from a strobila at stage II<sub>1</sub> immediately after the 1 min treatment with the thermomixer. B shows the regeneration of endoderm in the same specimen which has been cultured subsequently for a week.

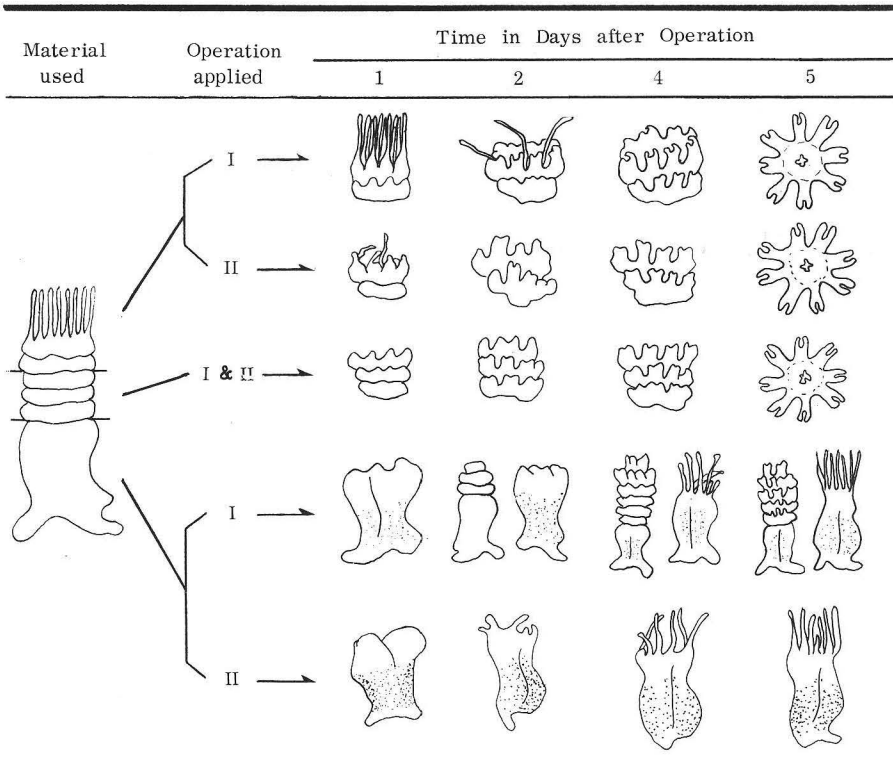

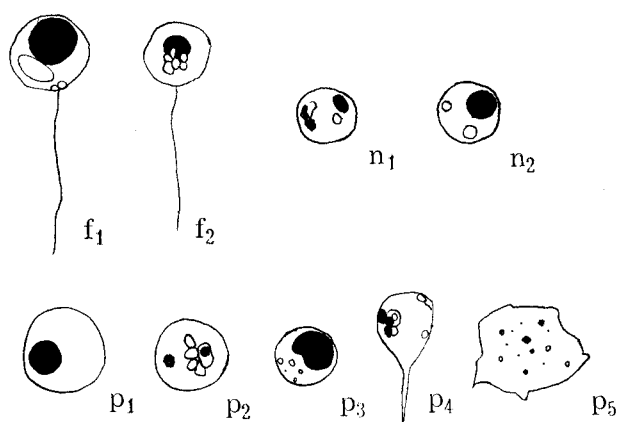

Fig. 6. Subsequent development of different parts of strobila which have been isolated from the individuals at stage II<sub>6</sub>. I and II mean the same as specified in the explanation of Fig. 4.

NODA (1971) obtained a reaggregated form from the dissociated cell aggregate and GIERER et al. (1972) also confirmed the same fact. But, no report is available concerned with the same kind of experiment using marine coelenterates. However, we succeeded in dissociating the *Aurelia* tissue into single cells by mechanical disruption. The procedure is rather simple. The cell suspension is obtained from the pieces or the whole body of *Aurelia* by shaking mechanically with the thermomixer for 2–3 min. But, when ephyrae were used as the material, 2 hrs pretreatment with trypsin is required for the successive mechanical disruption. The single cell suspension is dropped into the culture medium consisting of: ASW containing 1% calf serum, 50 unit per 1 ml of penicillin and 50  $\mu$ g per 1 ml of kanamycin. The suspension was adjusted to the level of  $2 \times 10^5$  to  $3 \times 10^5$  cells per 1 ml of the culture medium. Immediately after the dissociation, many cells turned into a spherical shape, then gradually became an

amaeoid shape extending filopodia- or pseudopodia-like processes. The suspended cells can be classified morphologically into four types except the statoliths (Fig. 7). Cell adhesion occurs mainly in the cell group which has affinity with Nile blue<sup>1)</sup>. Cytoplasmic processes hold an important role to initiate cellular contact at first, then proceed cellular adhesion. Fig. 8 demonstrates this process. Major fraction of these non-adhesive cells seems to be derived from the endoderm. Knowing the ectoderm in the polyp is the only structure which can be stained with Nile blue, the cell adhesion occurs mainly in the cell group derived from the ectoderm (A and B in Fig. 9 and Fig. 10). Statoliths do not participate actively in aggregate formation.

Small aggregate can be specified as the primary aggregate. There are definite differences in shape and size of the primary aggregates even at the beginning of aggregation, which can be seen within 3 hrs of incubation. The different types are distinguished and illustrated in Fig. 10. Characteristic behaviour of each type of the aggregates will become more prominent during the following 10 hrs in the culture. The first type is the growth of small primary aggregates through the direct contact with other cells. In this case, no fusion of primary aggregates is observed. This type usually happens in the culture of the polyp or ephyra cells. The second type could be described as follows: some of the peripheral cells of the aggregate become protruded and begin to contact with one or more aggregates, then form a bigger aggregate (C

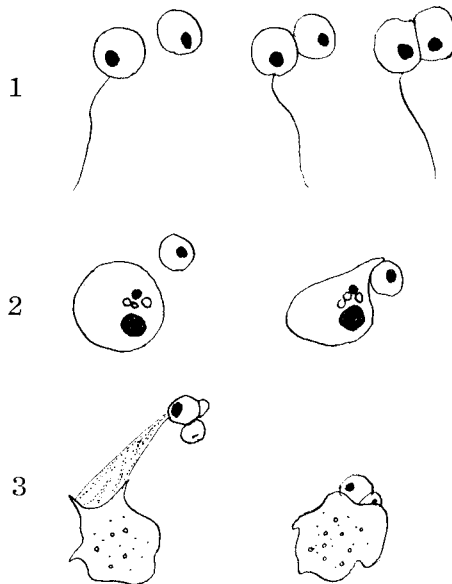

Fig. 8. Various examples of cell-adhesion found after the successful cell dissociation.

1) When the polyps are immersed in the very dilute Nile blue sulfate ( $8 \times 10^{-4}\%$ ) for 10 hrs and transferred to ASW, polyps will retain the dye exclusively in the ectoderm.

Fig. 9. A and B show the pattern of cell-adhesion in the suspension medium immediately after the cell dissociation. C and D show the intercellular contacts between the small primary aggregates which have been formed in one day culture. Test specimens were obtained from the strobila at stage II<sub>3</sub>.

and D in Fig. 9 and Fig. 10). This type is commonly observable in the cell aggregation from the young strobilae (stage II<sub>1-3</sub>). The third type is the direct growth of an amorphous primary aggregates. This is the case of aggregate formation of cells from the middle strobilae (stage II<sub>5</sub>-stage III<sub>8</sub>).

In the 3 to 5 day culture, the aggregates from the polyp cells and from the middle strobila-cells start to show characteristic features of a polyp such as the mouth opening and the peduncle formation (Fig. 11 and A,B and D in Fig. 12). We know, on the other hand, that the single or a few number of segments which have been separated from the strobilae (stage II<sub>5</sub>) will develop into ephyra (see p. 184 and Fig. 6 in this report; KATO, AOCHI and SAKAGUCHI, 1973). However, the failure of ephyra formation from the cell aggregate, which is derived from the strobilae, suggests to us that

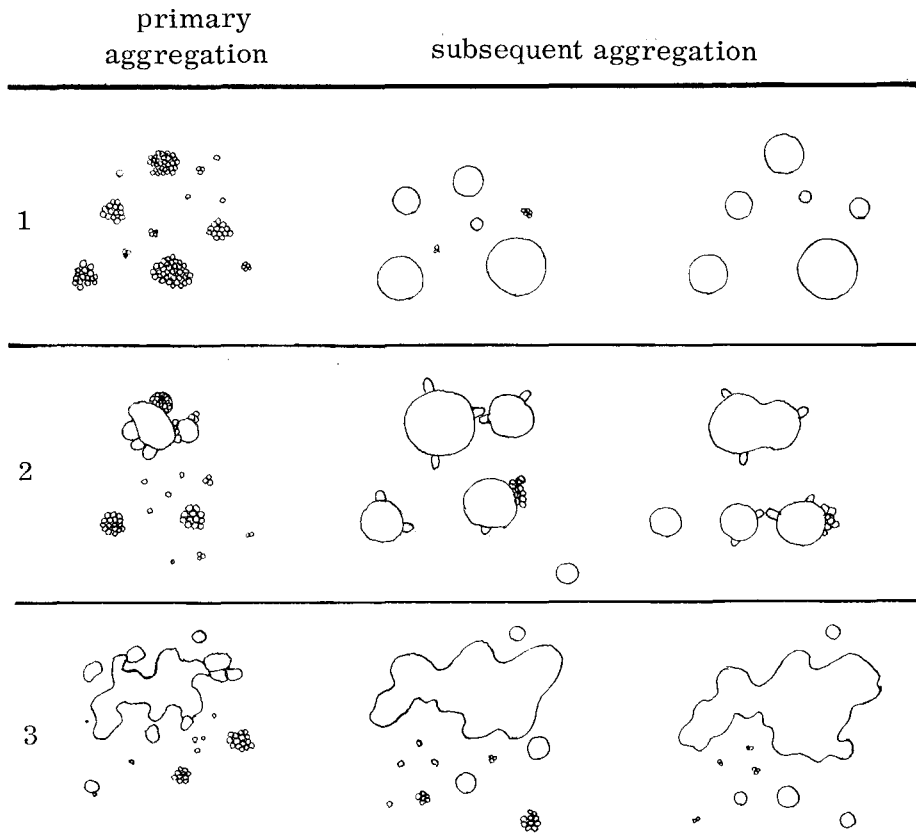

Fig. 10. Various courses of cell aggregates formation (cf. Text p. 188).

the dissociation procedure will damage the regulating factor(s) which might be essential to the cell groups to form the ephyra. When the aggregate is formed by the cells which are taken from the older strobilae (stage V) or the ephyra (stage VI), the aggregate becomes an irregularly shaped ball composed of a single epithelial layer like an outer layer of the normal ephyra (Fig. 11 and E in Fig. 12). Thus, it is plausible that the probable regulating factor which is implicated in the production of ephyra seems to be terminated at Stage IV. At the same time, it should be pointed out that the aggregate derived from the polyp-cells can regulate the formation of polyp holding a single axis, but the aggregate introduced from the strobila usually develops into a multi-axis polyp. In the latter case, many humps of the tentacle primordia occur on the body surface (Fig. 11, and C and D in Fig. 12). Such aggregates become separated eventually into several independent polyps. Strobilation can be considered as the process of establishment of many individuals through segmentation. The formation of the multi-axis polyps in the aggregate could reflect the intrinsic nature of the cells, which appears during the process of the strobilation. Reconstitution of cellular

architecture, which could correspond to a whole or a part of the polyp, seems to be achieved through intercellular communication. Analytical survey of the various reconstitution of the cell-aggregate in coelenterates will lead us to a better understanding of the mechanism of tissue development.

When the cells obtained from different stages were mixed and introduced to culture condition, the cells behave rather differently from the way described above. Partners for the combination experiment were altered case by case. Polyp cells were mixed with the cells which originated from either the strobila or ephyra, and another was the combination of cells from strobila and ephyra. Through these combination experiments, we found the following results: (1) cells derived from different stages can adhere each other and form an aggregate, and (2) the final status of the aggregate is always the same as the aggregate composed by aged material. It is highly probable that the cells obtained from different stages have an ability to communicate with each other; and furthermore, the cells lead the younger cells to transform into the more advanced structure in the aggregate.

### Summary

1. The morphological details of the process of strobilation in *Aurelia* are described and discussed.
2. Incorporation of radioactive precursors revealed that the nucleic acids synthesis was reached at maximum at strobila stage.
3. Removal of the endoderm in the polyp or young strobila will not allow them to continue the progress of strobilation. It suggests the existence of the regulation factor in the endoderm, which is necessary for further development.
4. Dissociated cells collected from the various stages show unique cellular behaviour for the aggregate formation.
5. It can be emphasized that the particular and characteristic pattern of strobilation in *Aurelia* could provide us useful tool to analyse the mechanism of cellular differentiation and tissue organization.

### Acknowledgements

The present authors wish to acknowledge their gratitude to Prof. Takasi TOKIOKA of the University of Kyoto who gave us encouragement and opportunity to present this paper on the Symposium. They would like to express their sincere appreciation to Prof. Hidemi SATO, University of Pennsylvania for his criticism and help in preparing the manuscript. Technical assistance was provided by Miss N. IZUHASHI and Miss M. KASUYA, to whom the authors wish to express their gratitude.

#### DISCUSSION

WERNER: Why is the region of highest concentration moving from the upper part to the lower parts in the process of strobilation? Is there a correlation with the regeneration process of the basal part into a new polyp?

KATO: This problem is quite difficult to explain. It is possible to say some physiological difference along the upper to the lower parts seems to be involved in the phenomenon. So far as the incorporation of the radioactive tracers is concerned, we found always much more grains in the upper part than in lower parts. We have some data that regenerative power declines as strobilation proceeds (KATO et al., 1973).

BRAVERMAN: We have found that blue dyed cells can be destroyed with a ruby raser, this may be of use to you in producing pure cell cultures. Your results are in part reminiscent of studies of DIEHL and BOVILLON.. They dissociated and recombined the cell layers of *Cordylophora*. Whether stolon or polyp formed depended on the proportion of epidermis or gastrodermis that is present.

KATO: Thank you for your valuable comment.

SATO: Would you have any more information concerning the special ectodermal protein which could be synthesized during the strobilation process? Say, for instance, molecular weight, the physico-chemical nature, and so on.

KATO: As I have mentioned, in electrophoretic study of the water soluble protein, we found four protein bands, and one of them would show strong phosphatase activity at both alkaline and acid pHs when the material was obtained from strobilae (the result was preliminarily reported in KATO and SENGEN, 1971, *Jap. Jour. Develop. Biol.*, 25:88—in Japanese). But, we do not have any detailed information at this moment, though further research of this particular protein is in progress.
