Abstract

In using a conventional LiPF₆/ethylene carbonate (EC)-dimethyl carbonate (DMC) electrolyte for lithium ion batteries (LIBs), a certain reductive reaction is known to occur at a relatively high potential (ca. 2.6 V vs. Li⁺/Li) on Sn electrode, but its details are still unknown. By means of in-situ X-ray reflectivity measurements, X-ray photoelectron spectroscopy, scanning electron microscopy observations and electrochemical measurements (by using mainly Sn electrode, and additionally Pt, graphite electrodes), we have found out that this reductive reaction eventually leads to the formation of an inactive passivated layer consisting mainly of insulative LiF ascribed to the reductive decomposition of LiPF₆, which significantly affects the cyclability of LIBs. In contrast, a solid-electrolyte interphase (SEI) is formed by the reductive reaction of the solvent at ca. 1.5 V vs. Li⁺/Li, which is unfortunately lower than the reduction potential of LiPF₆. However, we have found that the formation of SEI preempts that of the inactive surface layer when holding the electrode at a potential lower than 1.5 V vs. Li⁺/Li. Consequently, the battery cyclability is improved owing to the suppression of the formation of the inactive surface layer. Such a pretreatment before battery test would be quite effective on improvement of the battery cyclability, especially for a relatively noble electrode material whose oxidation potential is between 1.5 V and 2.6 V vs. Li⁺/Li.

1. Introduction

The surface layer, formed on a negative electrode by the reductive decomposition of an electrolyte in Li ion batteries (LIBs), passivates the electrode surface and prevents a further decomposition of the electrolyte on the surface. The surface layer having a good Li ion conductivity in addition to a sufficient electrical isolation[1,2] is often called “solid-electrolyte interphase (SEI)”. The properties of the surface layer dominate the various battery performances, e.g. the irreversible capacity, power and the degradation of the battery. Although there have been many works on those formed by the reduction reaction of the solvent[3–6], few studies have been reported on the influences on battery properties of a surface layer formed due to the decomposition of a solute. However, through an atomic force microscope observation, Lucas *et al.*[7] reported a certain small change on a surface of a Sn negative electrode at ca. 2.6 V vs. Li⁺/Li during cyclic voltammetry (CV) scan. It is expected that the surface morphologic change at the high potential can be ascribed to the reductive decomposition of the solute, because the potential of 2.6 V is higher than the reduction potential of the solvent, ca. 1.5 V vs. Li⁺/Li, at which the SEI is formed by the reductive reaction of the EC-DEC/DMC solvent (EC: ethylene carbonate, DEC: diethyl carbonate, DMC: dimethyl carbonate). However, the details of the reductive reaction at the relatively high potential has not been understood yet to date.

It is thus worthwhile to investigate a mechanism and influences on the battery properties of the reductive reaction around 2.6 V vs Li⁺/Li. In the present work, by using a two-electrode cell composed of a Sn electrode, a Li electrode, and a LiPF₆/EC-DMC electrolyte, we have found out that a considerably thick surface layer formed due to the reduction reaction at about/below 2.6 V in a two-electrode-CV profile. As demonstrated in the pioneering works,[8–10] the in-situ X-ray reflectivity (XRR) measurement is a quite suitable for analyzing characteristics of thin surface layers. Then, in combination with the in-situ XRR measurement, scanning electron microscopy (SEM), X-ray photoelectron spectroscopy (XPS), and conventional electrochemical measurements, here we have evaluated the properties (such as density, thickness, composition, etc.) of the surface layers formed on the electrode. Based on the results, we discuss a plausible formation mechanism of the surface layer on the electrode. In addition, LiClO₄ was also tested as a solute instead of LiPF₆ to check whether or not the surface layer is formed

without F ion species in the electrolyte. Furthermore, we have examined whether the similar surface layer is formed on Pt and graphite electrodes, instead of Sn. Finally, we mention the degradation behaviors in battery cycle tests by comparing two kinds of electrodes with the different surface layers formed by holding the electrodes at 2.0 V and 1.2 V, being higher and lower than the SEI formation voltage.

2. Experimental

2.1 Electrode preparation and battery construction

Flat and smooth Sn electrode samples for in-situ XRR measurements were prepared on a Si wafer by DC-magnetron sputtering at room temperature. For the XRR analyses, the sputtering time and the power were set at 300 s and 50 W, respectively. For the battery tests, a relatively thick Sn electrodes were prepared on Cu foils by sputtering for 900 s with 50 W. Pt plates mechanically polished with an emery paper were used for electrodes, and pyrolytic graphite plates (Panasonic) were used for graphite electrodes.

A two-electrode-cell consisting of the above electrodes as a “positive” electrode, a lithium metal sheet (Honjo Metal) as a “negative” electrode and an electrolyte with 1M LiPF₆ or 1M LiClO₄ (EC/DMC = 1/2 in volume, Kishida Chemical) were sealed in a laminated aluminum cell in an Ar-gas-filled glove box, where both moisture and oxygen content were less than 2 ppm. Water contents in the electrolytes were measured to be less than 80 ppm by Karl Fischer titrations (KEM, MKC-610). A cell/applied voltage set for the two-electrode-cell is, of course, not exactly equal to the value based on a Li reference electrode. However, since the current densities used in the present electrochemical measurements were small, so that the polarization of Li electrode is considered to be negligibly small, and we use the cell voltage in a unit of “V (vs. Li)”.

2.2 Electrochemical tests and In-situ XRR measurement

A cyclic voltammetry (CV) test and a battery cycle test were performed by a potentiostat/galvanostat (Biologic, VMP3), where the positive electrode was defined as a working electrode (WE) and the Li negative electrode was a counter/reference electrode (CE/RE); the two-electrode-CV scan was carried out from the initial OCV to 0.01 V at a sweep rate of 0.1 mVs⁻¹. In the battery charge/discharge cycle test, the current was set at

a rate of 1 C (0.07 mA cm^{-2}) for the Sn electrode, and the cut off voltages were set at 1.2 V and 0.01 V for charge and discharge, respectively. The Sn electrodes for the battery tests were prepared by holding them at 2.0 and 1.2 V for 5 h before the tests to compare the effects of the surface layers formed at these two potentials on the battery cyclability.

Parallel and monochromatic Mo $K\alpha$ radiation was obtained for XRR measurements by using the rotating anode X-ray generator, RINT-2500 (RIGAKU), with a Ge(111) single crystal incident monochromator. In-situ XRR profiles for the working electrode were obtained by decreasing the cell voltage from the initial open circuit voltage (OCV = 2.80 V) with a potentiostat/galvanostat (Biologic, SP200); to obtain each XRR profile, the positive electrode was kept for 30 min at each voltage, where each step was 25 mV, corresponding to the average scan rate of 0.014 mVs^{-1} .

2.3 SEM observation and XPS analyses

Images of surface and cross section of the electrodes were observed by a field-emission scanning electron microscopy (JEOL JSM-6500F). For the FE-SEM observation, two kinds of discharged (lithiated) Sn electrodes were prepared by holding the electrodes at 2.55 V and 1.2 V for 12 h in the LiPF_6 electrolyte, respectively. The electrode samples were taken out from the cell, washed by the solvent (EC/DMC = 1/2 in v/v) and then by DMC in the glove box, dried for 1 h in vacuum, and transported to the SEM in an Ar gas atmosphere.

Chemical bondings of the surface layer formed on the Sn electrode were investigated by X-ray photoemission spectroscopy (XPS, JEOL JPS-9010TRX) with Mg $K\alpha$ radiation (1254 eV), and those of the bulk (or near the Sn bulk) were also evaluated from the profiles after etching by Ar-ion sputtering at 300 eV. The electrode samples for the XPS analyses were prepared in the same procedure as those for the SEM observations; the typical samples were prepared by holding at 2.0 V and 1.2V for 12 h in the same electrolyte. The energy calibration was done with Si 2p (99.7 eV) coming from the Si wafer.

3. Results

Figure 1 shows the CV profile obtained for the Sn electrode. The profiles below 0.77 V show the typical CV for the formation of Sn-Li compounds.[3,11,12] In the higher voltage region, three cathodic peaks are observed at 1.40, 1.70, and 2.55 V in the first cycle. The peaks at 1.40 and 1.70 V (“b”, surrounded by a solid line square) are ascribed to the formation of a surface layer (so-called SEI) due to the reduction reaction of the solvent[6,13,14]. As before, in the present study, we focus the surface layer formed at about 2.55 V (“a” in Fig. 1).

Figure 2 compares the potential dependences of the charge amount by the reduction reaction on the Sn electrodes in the electrolyte with LiPF₆ (open circle) and LiClO₄ (black triangle). The cathodic peak at about 2.6 V was clearly observed in using the LiPF₆ electrolyte, while the peak around 2.6 V was not observed in the LiClO₄ electrolyte. Incidentally, the charge amount estimated for decomposition of the impurity water (less than 80 ppm) in the LiPF₆ electrolyte cannot explain the observed reduction charge amount around 2.6 V in Fig. 2. Thus, it is considered that the reduction reaction at 2.6 V originates from the solute LiPF₆.

Figures 3(a) and 3(b) show the in-situ XRR profiles of the Sn electrodes in the EC-DMC electrolyte with LiPF₆ and LiClO₄ at the voltages indicated by alphabets in Fig. 2, respectively. The XRR profiles at 0.145°, which corresponds to the critical angle θ_c of metal Sn in the electrolyte, remains virtually unchanged from “a” to “d” in Fig. 3(a). A drastic shift of the critical angle to a lower angle is observed in the voltage between “d” (2.6 V) and “e” (2.575 V), which indicates that a certain rough surface layer of low density was formed on the Sn electrode. In contrast, as found from Fig. 3(b), such a drastic profile change cannot be observed even when swept down to 2.0 V in using the LiClO₄ electrolyte. Thus, it can be concluded that the surface layer formed at 2.6 V is strongly related with the solute LiPF₆, namely, due to the reductive decomposition of the LiPF₆ solute. Figures 3(c) and 3(d) show the cross sections of (c) the as-sputtered electrode and (d) the electrodes taken out from the cell after being discharged from the initial OCV to 2.55 V. By comparing two micrographs, it is obvious that a rough surface layer about 200 nm thick is formed on the surface of the Sn electrode after swept down to 2.55 V.

As before, we can observe the other cathodic peaks around 1.5 V in the CV profile (“b” in Fig. 1), which is believed to be an SEI formation. Here, to distinguish the two kinds of surface layers, we have performed XPS measurements for the two samples

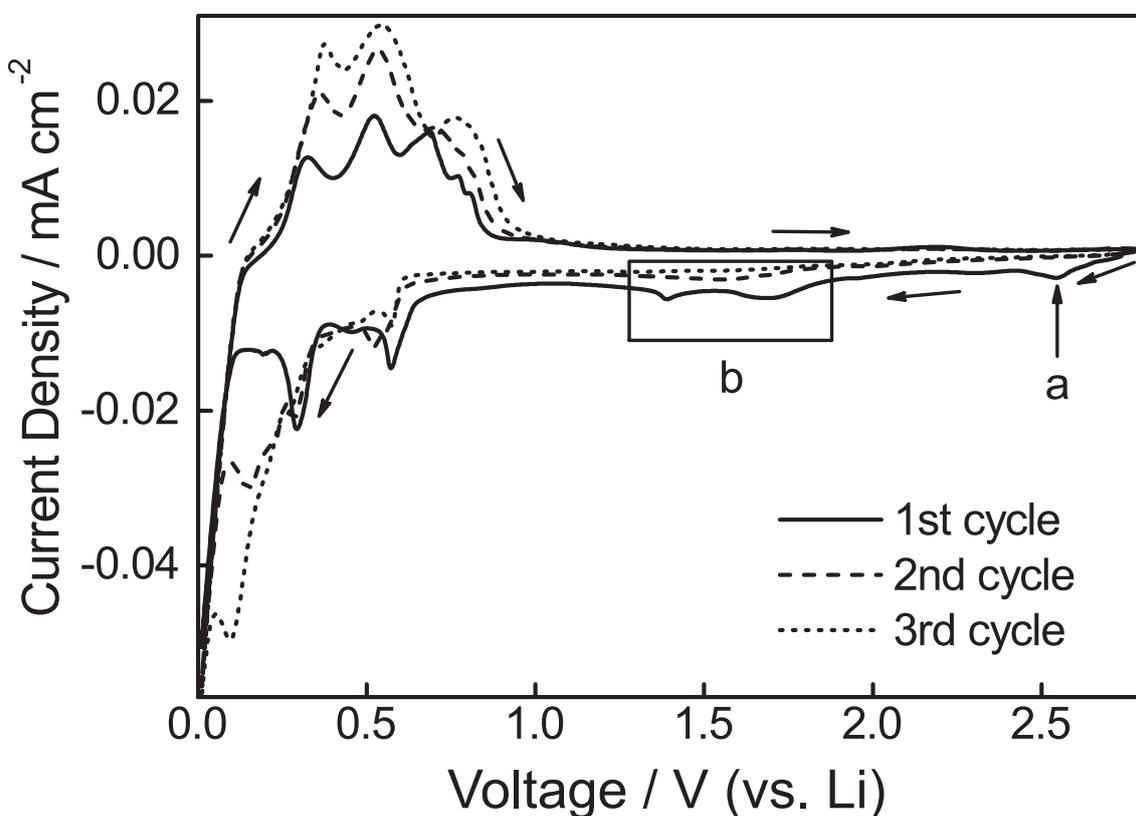

prepared by holding the electrodes at 2.0 V (> 1.5 V) and 1.2 V (< 1.5 V) in the LiPF₆ electrolyte. Figure 4 shows the chemical composition along the depth direction of the two surface layers formed at those voltages. As shown in Fig. 4(a) and 4(b), the elements Li, F, Sn, C, O and P were detected from both the samples. It is obvious that the thickness of the surface layer formed at 1.2 V is much thinner than that formed at 2.0 V. In the sample at 2.0 V, the signals from F, Li, and Sn are relatively strong, while C, O and P were weak and immediately vanished by Ar etching. On the other, in the sample at 1.2 V, since the signals from C and O were rather dominant even after the Ar etching for the duration longer than 10 min, this layer consists mainly of some organic material related to the solvent.

Figure 4(c) and (d) focus the F-Li and F-Sn bondings for non-etched and Ar-etched surfaces; hereafter we refer to the former as “just surface” and the latter as “near bulk”. In both samples prepared at 2.0 V and 1.2 V, while the XPS signal related with Sn-F is vanished completely near bulk (after the Ar etching for 5 min), the signal indicating Li-F remains with the Sn metal. We have clarified that the peak of the F 1s spectra near bulk is attributed to the LiF compound,[15,16] and the higher binding-energy peak of the Sn 3d spectra is attributed to the SnF₄ compound.[17,18] Thus, the surface layer formed at 2.0 V consists mainly of LiF and small amount of SnF₄ at just surface. In addition, as mentioned above, the surface layer formed at 1.2 V is much thinner than that at 2.0 V, because the relatively strong signal from the Sn metal can be observed other than SnF₄ even at just surface.

Here, as a supplementary experiment to check the universality of the reductive decomposition regardless of the kinds of electrodes, Pt and graphite electrodes were held at an appropriate voltage between 1.5 V and 2.6 V (here 2.0 V) for 12 h in the LiPF₆ electrolyte for the SEM observations. Figure 5 shows the SEM images of the Pt and graphite electrodes, after it was kept for 12 h at 2.0 V. By comparing Figs. 5(a) and 5(b), it is found that the Pt electrode was covered with a thick surface layer. Similarly, as seen in Figs. 5(c) and 5(d), a drastic change of the surface morphology is also observed on the graphite electrode. Especially in Pt electrode, we have also conducted the electrochemical quartz microbalance (EQCM) measurement by using a three-electrode cell (WE: Pt, CE, Li, RE: Li). Figure 6(a) and 6(b) show the EQCM profile and SEM microstructure. As found from Fig. 6(a), the mass change was drastically changed around 2.6 V with a large

cathodic current. In addition, as shown in Fig. 6(b), the electrode was covered with the thick surface layer; by the EDX analysis, the film composition was measured to be F: 93.4 at%, P: 1.6 at%, Pt: 4.7 at%, which indicates that the Pt electrode is substantially covered by the surface layer. Since the chemical composition of P is very small compared to that of F, the surface layer was not composed of PF_6^- or PF_3 , and mainly composed of LiF (Li cannot be detected by the EDX analysis). Thus, it has been demonstrated that the formation of such a surface layer at the high potentials was observed even in Pt and also graphite electrode, and may be universal irrespective of the kinds of electrodes.

Finally, to examine the influences of the surface layers on battery performances, we have carried out the battery cycle tests by u

sing two kinds of the Sn electrodes prepared at 1.2 V and 2.0 V for 5 h in the LiPF_6 electrolyte. The difference of the battery capacities of the Sn electrodes is shown in Fig. 7. Obviously, the electrode held at 2.0 V is promptly degraded because of the presence of the surface layer consisting mainly of LiF, while the electrode kept at 1.2 V shows a relatively good cyclability. This difference is maybe due to the polarization difference (namely, polarization becomes large in the case of the electrode prepared at 2.0V), which influences the charge/discharge amount till the cut-off voltage in cycling process.

4. Discussion

By in-situ XRR technique, we have found that the long-time holding of the electrode in the LiPF₆/EC-DMC electrolyte between 1.5 and 2.6 V eventually leads to the formation of a thick inactive passivated layer on the electrode surface. This behavior is considerably universal without regard to the kinds of electrodes. Namely, the surface layer formed by holding at 2.0 V was also observed on Pt and graphite electrodes as well as on the Sn electrode.

Taking account of the high chemical durability of the EC/DMC solvent at 2.55 V vs. Li⁺/Li[13] and the absence of the surface-layer with the use of LiClO₄ instead of LiPF₆, the surface layer consisting mainly of LiF is considered to originate from the reductive decomposition of the LiPF₆ solute. According to literature,[15] a plausible main reductive reaction of the solute is considered to be

Namely, when LiPF₆ is reduced to be PF₃, the F⁻ ions are released and instantly the LiF compound can be formed on the electrode surface with Li ions in the electrolyte. Thus, the fact that the LiF formation occurs at the relatively high potential around 2.0-2.5 V can be understood as a consequence of the reductive reaction of the PF₆⁻ anion.

Besides the main reaction, we have to mention the formation mechanism of the SnF₄ compound. Basically, SnF₄ would be formed by a chemical reaction with hydrogen fluoride HF. It is reported that LiPF₆ is decomposed, with moisture impurity in the electrolyte, to LiPF₆ + H₂O → LiF + 2HF + PF₃O, where the product HF reacts with the Sn electrode to form the SnF₄ compound[19,20]. An unavoidable small amount of the water always exists in the electrolyte (actual content of moisture was about 80 ppm in this study) even though we carefully treat battery components in an Ar-filled dried globe box (dew point less than -82 °C). Under the existence of H₂O, LiPF₆ decomposes to give various chemical components, which would result in the formation of SEI-like deposits. Hence, it is necessary to take the above reaction into consideration here. However, it should be noted that the above reaction is not an electrochemical reaction governed by the electrode potential, so that this reaction may not be involved with the thick surface-layer formed at such a high potential of 2.6 V. Actually, the SnF₄ compound was observed

on “just surface” and not observed “near bulk”. Thus, the electrochemical inactive surface layer would be due to the reductive reaction at the relatively high potential.

Then, we encounter a problem of how to suppress the surface-layer formation due to the reduction of LiPF₆. When the electrode is held below 1.5 V (e.g., at 1.2 V in the present experiment), not only the reductive reaction of the solvent for the formation of the SEI layer, but also that of the LiPF₆ can occur *in principle* electrochemically. However, as shown in the SEM and XPS observations above, the surface layer formed at 1.2 V is much thinner than that formed at 2.0 V, and its composition is very different from the layer formed at 2.0 V. As a consequence, we have obtained a significant fact that the reductive reaction of the EC-DMC solvent preempts that of the LiPF₆ solute below 1.5 V. Although the surface layer consisting mainly of insulative LiF (and also SnF₄) seriously affects the battery performance, the electrode can circumvent the formation of the inactive passivated layer by holding at 1.2 V prior to the battery test, by which the cyclability of the Sn electrode is significantly improved. Thus, such a pretreatment would be quite effective on the suppression of the inactive surface-layer formation and improvement of the battery cyclability.

5. Conclusions

We have investigated the formation of the inactive surface layer formed at a relatively high potential in the commonly used LIB systems. In the present experiment, the cathodic peak observed around 2.6 V is found to form the inactive surface layer consisting mainly of LiF, being due to the reductive decomposition of the LiPF₆ solute, which affects battery performances. Although the reduction potential is much higher than the well-known potential of 1.5 V for the SEI formation, it has been demonstrated that the SEI formation precedes the inactive surface-layer formation that originates from the reductive decomposition of LiPF₆. This is a very important result for development of the LIB negative electrode, since the battery cyclability is significantly improved by the low-potential-holding pretreatment, as demonstrated in the present study. Thus, in order to obtain an excellent battery cyclability, it is recommended to be held at an appropriate potential below 1.5 V vs. Li⁺/Li to form the SEI layer on a negative electrode.
