30 **Abstract**

31 Gaze and arrows automatically trigger attentional shifts. Neuroimaging  
32 studies have identified a commonality in the spatial distribution of the neural  
33 activation involved in such attentional shifts. However, it remains unknown  
34 whether these activations occur with common temporal profiles. To  
35 investigate this issue, magnetoencephalography (MEG) was used to evaluate  
36 neural activation involved in attentional shifts induced by gaze and arrows.  
37 MEG source reconstruction analyses revealed that the superior temporal  
38 sulcus and the inferior frontal gyrus were commonly activated after 200 ms, in  
39 response to directional versus non-directional cues. Regression analyses  
40 further revealed that the magnitude of brain activity in these areas and in the  
41 bilateral occipital cortex was positively related to the effect of attentional  
42 shift on reaction times under both the gaze and the arrow conditions. The  
43 results also revealed that some brain regions were activated specifically in  
44 response to directional versus non-directional gaze or arrow cues at the  
45 350–400-ms time window. These results suggest that the neural mechanisms  
46 underlying attentional shifts induced by gaze and arrows share  
47 commonalities in their spatial distributions and temporal profiles, with some  
48 spatial differences at later time stages.

## 52 **1 Introduction**

53       Sharing attention with others allows individuals to share critical  
54 information regarding the environment and to respond appropriately in  
55 coordination with others. Gaze direction provides information about the  
56 direction of others' attention (Emery, 2000), and behavioral studies have  
57 shown that the eye gaze of others triggers attentional shifts (Frischen et al.,  
58 2007). For example, Friesen and Kingstone (1998) presented gaze cues at the  
59 center of a screen. Subsequently, a target appeared to the left or the right of  
60 the cue. Participants were asked to detect, localize, and identify the  
61 subsequent target. The results revealed that participants showed a shorter  
62 reaction time (RT) to gaze-at-targets (i.e., valid condition) than to  
63 non-gaze-at-targets (i.e., invalid condition). Attentional shifts occurred even  
64 when the cues were counterpredictive of the target locations (Driver et al.,  
65 1999) or were presented without the conscious awareness of the participant  
66 (Sato et al., 2007). These data indicate that gaze automatically triggers  
67 attentional shifts.

68       Symbols, such as arrows, are also important cues that signal attentional  
69 direction. Pioneering studies have demonstrated that arrows trigger  
70 attentional shifts only when participants intend to follow the direction of the  
71 cues (e.g., Posner, 1980). In line with this, some behavioral studies have  
72 demonstrated that, unlike gaze cues, arrow cues did not induce reflexive  
73 attention orienting in some situations; arrow cues did not trigger attention

74 orienting when they were counterpredictive of a target location (Friesen et al.,  
75 2004) or had different characteristics (e.g., color) than that of the target  
76 (Ristic et al., 2007). Further, a recent study found a right-lateralized  
77 hemispheric asymmetry for attention orienting by gaze but not by arrow cues  
78 (Greene and Zaidel, 2011), suggesting that different psychological  
79 mechanisms were involved in the two types of cueing. However, other  
80 studies have shown that arrow cues automatically trigger attentional shifts in  
81 the same manner as do gaze cues (Hommel et al., 2001 and Tipples, 2002).  
82 Several recent studies have compared the behavioral effects of gaze and arrow  
83 cues using the cueing paradigm (Sato et al., 2010; Stevens et al., 2008 and  
84 Tipples, 2008). These studies found that both types of cues trigger  
85 attentional shifts even when they are counterpredictive of target locations  
86 (Tipples, 2008), induce enhanced response speed but not enhanced accuracy  
87 when discriminating the target following the cue (Stevens et al., 2008), and  
88 have comparable sensitivity to the stimulus onset asynchrony between cues  
89 and targets (Sato et al., 2010). These data suggest some common features in  
90 the psychological mechanisms underpinning the automatic attentional shifts  
91 triggered by gaze and arrows.

92       Recent functional magnetic resonance imaging (fMRI) studies have  
93 investigated the neural activity underlying the attentional shifts induced by  
94 gaze and arrow cues. Hietanen et al. (2006) demonstrated activation of the  
95 middle/inferior occipital area by gaze cues, whereas arrow cues induced

96 activity in these regions as well as in areas in the fronto-parietal cortex.  
97 However, other fMRI studies have revealed common patterns of neural  
98 activation underlying the attentional shifts induced by gaze and arrows  
99 (Tipper et al., 2008 and Sato et al., 2009). Tipper et al. (2008) presented an  
100 ambiguous cue stimulus in the cueing paradigm and asked participants to view  
101 the cue stimulus as either an eye or an arrow. This study found that the  
102 distributed frontoparietal and posterior regions, which include the inferior  
103 frontal gyrus (IFG), posterior superior temporal sulcus (STS), inferior  
104 parietal lobule (IPL), and inferior occipital gyrus (IOG), were commonly  
105 activated during attentional shifts following gaze and arrow cues. Sato et al.  
106 (2009) investigated neural activation while participants passively observed  
107 the directional and non-directional cues of gaze and arrows. Brain regions,  
108 including the IOG, STS, IPL, and IFG in the right hemisphere, were  
109 commonly activated in response to directional versus non-directional gaze  
110 and arrow cues. In a study comparing gaze cues and different non-gaze cues  
111 (i.e., peripheral squares), Greene et al. (2009) also demonstrated that these  
112 two types of cues activated largely overlapping brain regions covering the  
113 aforementioned areas. Although these studies also found differences in  
114 neural activity in response to gaze and arrow cues (Sato et al., 2009 and  
115 Tipper et al., 2008), brain regions which showed distinct activations to gaze  
116 and arrow cues were not consistent across studies. These findings suggest  
117 that attentional shifts induced by gaze and arrow cues are implemented by the

118 activation of common as well as different neural mechanisms.

119       However, due to the limited temporal resolution of the fMRI technology,  
120 questions about whether the neural activation in response to gaze and arrow  
121 cues occurs with common temporal profiles have remained unanswered.  
122 Commonalities in the spatial distribution of neural activations do not  
123 necessarily indicate a commonality of temporal profiles. Electrophysiological  
124 recordings, including electroencephalography (EEG) and  
125 magnetoencephalography (MEG), are appropriate tools to measure brain  
126 activity with high temporal resolution. A few previous EEG studies have  
127 investigated the processing of gaze and arrow cues (Brignani et al., 2009 and  
128 Hietanen et al., 2008). Brignani et al. (2009) evaluated neural responses in the  
129 cueing paradigm using directional gaze and arrows. Consistent with the  
130 results of the fMRI studies (Sato et al., 2009 and Tipper et al., 2008), similar  
131 spatial and temporal patterns of EEG activation were found in the posterior  
132 and frontal regions in response to directional cues. Hietanen et al. (2008)  
133 presented directional and non-directional gaze and arrow cues and found that  
134 some components in temporoparietal sites, specifically after 200 ms, were  
135 commonly activated in response to directional versus non-directional cues. A  
136 recent MEG study also compared the brain responses to gaze cues and to  
137 non-gaze cues (i.e., peripheral squares) and found very similar patterns in  
138 the time course of global field power (Nagata et al., 2012). In summary,  
139 these data suggest a certain level of commonality in the temporal profiles of

140 brain activation in response to gaze and arrow cues. However, because of  
141 limitations in the spatial resolution of electrophysiological measures (Dale  
142 and Halgren, 2001), it remains unclear whether the activation of the specific  
143 brain regions identified in fMRI studies (Sato et al., 2009 and Tipper et al.,  
144 2008) exhibited common temporal profiles in response to gaze and to arrows.

145 In this study, we recorded MEG signals and conducted  
146 source-reconstruction analysis using fMRI data (Litvak et al., 2011) to  
147 investigate the temporal profiles of the neural activation involved in  
148 attentional shifts induced by gaze and arrows. Directional and  
149 non-directional gaze and arrow cues were presented, and participants were  
150 asked to localize the peripheral target as quickly and accurately as possible.  
151 Temporal profile analyses for the MEG signals in response to the directional  
152 and non-directional gaze and arrow cues were conducted in spatially restricted  
153 brain regions (i.e., the IOG, STS, IPL, and IFG) derived from a previous fMRI  
154 study (Sato et al., 2009). It was predicted that these brain regions would show  
155 a common temporal activation in response to directional versus  
156 non-directional cues. Regression analyses between brain activation and  
157 behavioral data were also conducted to test the prediction that the neural  
158 activation would be related to behavioral attentional shifts.

159 Additionally, we explored differences in the temporal pattern of  
160 activations in response to gaze and arrows. Based on previous behavioral  
161 (Friesen et al., 2004 and Ristic et al., 2007) and fMRI (Hietanen et al., 2006;

162 Tipper et al., 2008 and Sato et al., 2009) studies, it is plausible that the gaze  
163 and arrow cues could activate distinct in addition to common neural  
164 mechanisms. We explored the different spatiotemporal profiles of the MEG  
165 signals in response to gaze and arrow cues in the superior parietal lobule  
166 (SPL), the precentral gyrus (PCG), and the middle temporal gyrus (MTG),  
167 areas identified by a previous fMRI study (Sato et al., 2009).

168

## 169 **2 Materials and methods**

### 170 *2.1 Participants*

171 Eighteen volunteers participated in the study. All participants were  
172 right-handed, as assessed by the Edinburgh Handedness Inventory (Oldfield,  
173 1971), and had normal or corrected-to-normal visual acuity. All participants  
174 provided written informed consent prior to participation in this study, which  
175 was approved by the ethics committee of the Primate Research Institute,  
176 Kyoto University.

177 We analyzed the data from 13 volunteers (nine males; mean  $\pm$  *SD* age  
178  $27.6 \pm 5.8$  years). Five volunteers (two females and three males) were  
179 excluded from the MEG analysis because the RT differences between invalid  
180 and valid conditions were not above zero, indicating no attentional shifts to  
181 the cued location under either gaze or arrow conditions. Our preliminary  
182 analyses confirmed that the same RT patterns were found even when these  
183 participants were included in the analyses.

184 *2.2 Design*

185           The experiment was constructed using a within-participant  
186 two-factorial design; cue type (gaze or arrow) and cue direction (directional  
187 or non-directional).

188 *2.3 Stimuli*

189           Gaze and arrow stimuli (Fig. 1) utilized by previous studies (Sato et al.,  
190 2009 and Sato et al., 2010) were employed here. These studies confirmed that  
191 these gaze and arrow cues trigger the same degree of attentional shift.

192           For directional gaze cues, we prepared gray-scale photographs consisting  
193 of full-face neutral expressions displayed by three females and three males  
194 looking left. Mirror images of these stimuli were created using Photoshop 6.0  
195 (Adobe), and these were used as the stimuli indicating the right direction. For  
196 non-directional gaze cues, photographs of full-face neutral faces gazing  
197 straight ahead were also prepared.

198           For directional arrow cues, we created left-pointing stimuli consisting  
199 of horizontal lines subtending  $4.0\text{--}8.0^\circ$  horizontally with two oblique lines  
200 that tilted  $30\text{--}60^\circ$  from the horizontal line. Mirror images of these stimuli  
201 were created and used as right-pointing stimuli. Non-directional arrow cues  
202 were also prepared. Finally, a lozenge was constructed using the same  
203 horizontal and oblique lines that were used for the directional stimuli.

204           All stimuli were depicted within a rectangle, subtending  $12.5^\circ$  vertical  
205  $\times 10.0^\circ$  horizontal, on a gray plane background. The mean luminance of all

206 images was made constant using MATLAB 6.0 (Mathworks).

207 \*\*\*\*\*

208 Figure 1

209 \*\*\*\*\*

#### 210 2.4 Apparatus

211 Events were controlled by Presentation software (version 10.0;  
212 Neurobehavioral System) implemented on a Windows computer. The stimuli  
213 were projected from a liquid crystal projector (DLA-G150CL; Victor) to a  
214 mirror that was positioned in front of the participants.

#### 215 2.5 Procedures

216 In each trial, after a crosshair was presented at the center of the screen  
217 for 500 ms, a gaze or arrow cue (right, left, or non-directional) was  
218 presented at the same location for 500 ms. Then, the target letter “T”  
219 appeared to the left or the right side of the cue stimulus (Fig. 2). The  
220 presented cue did not predict the target location. Thus, the target appeared to  
221 each side of the cue stimulus 50% of the time. The participants were asked to  
222 specify as quickly and accurately as possible whether the target appeared on  
223 the left or the right side of the screen by pressing the corresponding button  
224 on the switch box using the right index or middle finger, respectively. The  
225 interval from target appearance to button response was measured. The target  
226 and cue remained on the screen until a response was made; if 1000 ms  
227 elapsed with no response, the target disappeared. After an 800–1200-ms

228 inter-trial interval, the next trial started. The participants were told that the  
229 cues did not predict the target location and were instructed to fixate on the  
230 center of the screen.

231 The experiment consisted of gaze and arrow blocks, and block order  
232 was counterbalanced across participants. Each block included six blocks of  
233 36 trials. Thus, a total of 432 trials (72 trials each for valid-gaze,  
234 invalid-gaze, non-directional-gaze, valid-arrow, invalid-arrow, and  
235 non-directional-arrow condition) were conducted. The trials were presented  
236 in random order, and participants were allowed to rest between blocks.  
237 Twenty practice trials preceded the experimental trials.

238 \*\*\*\*\*

239 Figure 2

240 \*\*\*\*\*

## 241 2.6 MEG acquisition

242 MEG acquisition was performed in an electromagnetically shielded  
243 room using a 210-channel whole-head supine-position system (PQ1400RM;  
244 Yokogawa). A forehead strap was used to stabilize head position. MEG data  
245 were sampled at 1000 Hz through a band-pass of 0.05–200 Hz. Vertical and  
246 horizontal electrooculograms (EOGs) were simultaneously recorded.

247 To measure head position within the MEG sensor system, five  
248 calibration coils were mounted on the participants' heads. An  
249 electromagnetic calibration of the coil positions was performed before each

250 MEG recording session. Participants' head shape and calibration coil  
251 positions were digitized with a three-dimensional (3D) laser-optical scanner  
252 and a stylus marker (FastSCAN Cobra; Polhemus) and were later used to  
253 co-register the MEG sensor locations to an anatomical space defined by an  
254 individual MRI.

### 255 *2.7 Anatomical MRI acquisition*

256 Anatomical MRI acquisition was performed on a 3 T scanning system  
257 (MAGNETOM Trio A, Tim System; Siemens) using a 12-channel head coil  
258 with a forehead pad used to stabilize head position. A T1-weighted  
259 high-resolution anatomical image was obtained using a  
260 magnetization-prepared rapid-acquisition gradient-echo (MP-RAGE)  
261 sequence (TR = 2250 ms; TE = 3.06 ms; IT = 900 ms; flip angle = 9°; field of  
262 view = 256 × 256 mm; voxel size = 1 mm × 1 mm × 1 mm).

### 263 *2.8 Data analysis: behavioral performance*

264 Data were analyzed using SPSS 10.0J (SPSS; Japan). As in previous  
265 studies (e.g., Langtone and Bruce, 1999), the median RT of correct responses  
266 was calculated for each condition and analyzed using a 2 (cue type) × 3  
267 (cue-target validity) repeated-measures analysis of variance (ANOVA). In  
268 cases in which the assumption of sphericity was not met ( $p < 0.05$ ,  
269 Mauchley's sphericity test), the Greenhouse–Geisser adjusted degree of  
270 freedom was used. Multiple comparisons were performed using Ryan's  
271 method. To confirm the results in the absence of parametric assumptions, we

272 also performed Wilcoxon signed-rank tests. The results of all tests were  
273 considered statistically significant at  $p < .05$ .

## 274 2.9 Data analysis: MEG preprocessing and source reconstruction

### 275 2.9.1 Commonality.

276 Data analysis was conducted using Statistical Parametric Mapping  
277 software (SPM8 r4290; <http://www.fil.ion.ucl.ac.uk/spm/>). Continuous MEG  
278 data were epoched into 500-ms segments for each trial and down-sampled to  
279 200 Hz; pre-stimulus baseline data were collected for 50 ms, and  
280 experimental data were collected for 450 ms after cue stimulus onset. The  
281 data were initially subjected to independent component analyses (ICA) for  
282 the purpose of artifact rejection using EEGLAB toolbox  
283 (<http://sccn.ucsd.edu/eeglab/index.html>). The ICA components (ICs) were  
284 visually inspected, and those representing eye artifact, heartbeat, or muscle  
285 activities were rejected. The rest of the ICs were projected back to the MEG  
286 sensor space to obtain a “clean” MEG signal. Threshold-based artifact  
287 rejection was also conducted. Any epochs containing a gradiometer  
288 amplitude  $\geq 3000$  fT/cm and an absolute EOG amplitude  $\geq 80$   $\mu$ V were  
289 rejected as artifacts. The number of artifact-contaminated trials did not  
290 differ across conditions (mean  $\pm$  SD =  $8.56 \pm 4.66$ ;  $p > 0.1$ ,  
291 within-participant ANOVA). The pre-processed data were then low-pass  
292 filtered at 48 Hz, baseline corrected on the basis of the 50-ms pre-stimulus  
293 period, and averaged over trials by conditions for the following analyses.

294 For fMRI-constrained MEG source reconstruction, the restricted  
295 solution approach implemented in SPM8 (Litvak et al., 2011) was used,  
296 where a “hard” spatial prior derived from fMRI studies was imposed to solve  
297 the MEG inverse problem with a reduced source space. First, the cortical  
298 mesh on which the current dipoles were placed was created. The individual  
299 anatomical MRI of each participant was segmented and spatially normalized  
300 to the Montreal Neurological Institute (MNI) space. The inverse of this  
301 normalization transformation was then used to warp a canonical cortical  
302 mesh in the MNI space to the individual cortical mesh (Mattout et al., 2007).  
303 The cortical mesh described the source locations with 20,484 vertices (i.e.,  
304 “fine” size). Next, the MEG sensors were co-registered to anatomical MRI  
305 data by matching the positions of three fiducials (nasion and R- and  
306 L-preauricular points) and head shape. The forward model could then be  
307 computed using a “single sphere” model by assuming that the orientations of  
308 the sources were normal to the cortical mesh.

309 The forward model was inverted using a parametric empirical Bayesian  
310 framework (Mattout et al., 2007) with the optimization of Multiple Sparse  
311 Priors (MSP) by a greedy search algorithm (Friston et al., 2008). To  
312 investigate the commonality of the brain activities induced by gaze and  
313 arrows, the inverse reconstruction used to compute cortical source activities  
314 was restricted to eight predefined regions of interest (ROIs; i.e., restricted  
315 solution approach). Based on a previous fMRI study (Sato et al., 2009), the

316 brain regions that were more activated in response to directional versus  
317 non-directional gaze and arrow cues were selected. The center coordinates  
318 for the IOG, STS, IPL, and IFG in the right hemisphere were selected. A  
319 sphere with a 24-mm radius centered on the coordinates of each area was  
320 created. Although the original study (Sato et al., 2009) reported activation in  
321 only the right hemisphere, the hemispheric functional asymmetry in fMRI  
322 (Tipper et al., 2008), EEG (Brignani et al., 2009 and Hietanen et al., 2008)  
323 and behavioral studies (Greene and Zaidel, 2011 and Okada et al., 2012) is  
324 inconsistent, and thus, data from the IOG, STS, IPL, and IFG of both  
325 hemispheres (IOG:  $x = \pm 36$ ,  $y = -86$ ,  $z = -8$ ; STS:  $x = \pm 64$ ,  $y = -46$ ,  $z = 16$ ;  
326 IPL:  $x = \pm 42$ ,  $y = -48$ ,  $z = 46$ ; IFG:  $x = \pm 48$ ,  $y = 24$ ,  $z = 20$ ) were used by  
327 flipping ROIs in the right hemisphere based on MSP generation (cf. Henson  
328 et al., 2009). The parameters of the inversion were based on SPM default  
329 settings with the exception of not using a Hanning taper for the time series.

330 For every participant and condition, 3D source-reconstructed images in  
331 the MNI standard space of evoked activity were obtained every 50 ms  
332 between 0 and 400 ms in the post-stimulus window. The intensity was  
333 normalized to the mean over voxels and conditions to reduce  
334 inter-participant variance. All images were smoothed by 8 mm in the  
335 conversion from a cortical mesh to the MNI voxel space.

### 336 2.9.2 *Difference.*

337 The same method used for the commonality analysis was used to

338 explore differences in brain activities in response to gaze and arrow cues.  
339 One exception was that the inverse reconstruction used to compute cortical  
340 source activities was restricted to other ROIs. Based on a previous fMRI  
341 study (Sato et al., 2009), three brain regions (the left-hemisphere SPL, the  
342 left-hemisphere PCG, and the right-hemisphere MTG) that showed different  
343 activation in response to gaze and arrow cues were selected. Another fMRI  
344 study also found differences in the MTG and the PCG (Hietanen et al., 2006).  
345 The center coordinates in both hemispheres were used for the SPL, PCG, and  
346 MTG (SPL:  $x = \pm 16$ ,  $y = -52$ ,  $z = 46$ ; PCG:  $x = \pm 32$ ,  $y = 8$ ,  $z = 42$ ; MTG:  $x =$   
347  $\pm 52$ ,  $y = -66$ ,  $z = 2$ ) by flipping ROIs in each hemisphere.

## 348 *2.10 Data analysis: MEG regional brain activity analysis*

### 349 *2.10.1 Commonality.*

350 The source-reconstruction images were entered into the random-effects  
351 general linear model (GLM) as repeated-measures factors including cue type  
352 (gaze vs. arrow), cue direction (directional vs. non-directional), and time  
353 window (0–50, 50–100, 100–150, 150–200, 200–250, 250–300, 300–350, and  
354 350–400 ms); participant was a factor of no interest. The ensuing covariance  
355 components were estimated using a restricted maximum likelihood procedure  
356 to adjust the statistics. The low-variance regions, which can cause  
357 artificially high statistical values and localization bias, were also adjusted  
358 (Ridgway et al., 2012).

359 Planned contrasts were performed for each time window. Based on the

360 objectives of the current study, the common activity associated with the  
361 effect of cue direction (directional vs. non-directional) across cue types  
362 (gaze and arrow) was tested using a conjunction analysis with interaction  
363 masking (Nichols et al., 2005 and Price and Friston, 1997; cf. Sato et al.,  
364 2009). First, the contrast of directional gaze versus non-directional gaze  
365 (contrast 1) and directional arrow versus non-directional arrow (contrast 2)  
366 was specified, and then the main effect of contrast 1 + 2 was exclusively  
367 masked by the *F*-tests of interactions (i.e., a two-tailed test of contrast 1 -  
368 contrast 2). The significance threshold of the masking was set to  $p < 0.05$   
369 (uncorrected). Significantly activated voxels were identified if they reached  
370 the extent threshold of 10 voxels with a height threshold of  $p < 0.05$   
371 (uncorrected). To display the activation, the root-mean-square (RMS) time  
372 course of MEG source activities within a 4-mm radius of the peak foci was  
373 extracted between 0 and 400 ms for each participant and averaged across  
374 participants.

375       Additionally, multiple regression analyses were performed to  
376 investigate the relationships between MEG source activity and behavioral  
377 measures, specifically RT. First, subtraction images between the directional  
378 and non-directional condition in each time window were created for each cue  
379 type. RT ratios between invalid and valid conditions were also calculated for  
380 each participant under gaze and arrow conditions and used as a measure of  
381 the cueing effect. This method allowed controlling for baseline RT

382 difference across individuals to investigate the degree of attentional  
383 facilitation (c.f. Sereno and Holzman, 1996). Based on the results of the  
384 above conjunction analysis, we searched for voxels that showed a positive  
385 relationship between the source activity evoked by the directional cue and  
386 the cueing effect in the 200–250, 250–300, 300–350, and 350–400 ms time  
387 windows. Then, GLMs including the behavioral measure (cueing effect) as a  
388 covariate of interest and cue type (gaze and arrow) as a factor of interest  
389 were constructed; participant was a factor of no interest. To identify brain  
390 regions that exhibited the same relationship with the cueing effect under  
391 both gaze and arrow conditions, a conjunction analysis with interaction  
392 masking was conducted. The contrast of the positive regression slope with  
393 the cueing effect of gaze and arrow were masked by the  $F$ -tests of  
394 interactions (i.e., the differential regression slope between the cueing effect  
395 of gaze and arrow) in each time window. A significant activation was  
396 identified if the activation foci reached the height threshold of  $p < 0.05$  with  
397 the extent threshold of 10 voxels.

398 Preliminary analyses were also conducted for target-related activities  
399 (cf. Nagata et al., 2012). However, we found that the MEG signals were  
400 severely contaminated by noise related to eye movements and hand  
401 responses to peripheral targets even after the ICA preprocessing. The results  
402 also showed effects around eye regions. Thus, we did not report the  
403 target-related activity in this paper.

404 *2.10.2 Difference.*

405       The same GLM used in the commonality analysis was used in this  
406 analysis. First, the contrasts between directional gaze and non-directional  
407 gaze (contrast 1) and between directional arrow and non-directional arrow  
408 (contrast 2) were specified. To explore the differences in brain activity in  
409 response to gaze and arrow cues, we analyzed the specific instances in which  
410 higher activity was more strongly associated with one stimulus type than  
411 with the other. For example, the interaction involving higher activity  
412 specifically for directional gaze was tested as follows: [(directional eyes –  
413 non-directional gaze) – (directional arrow – non-directional arrow)].  
414 Significantly activated voxels were identified if they reached the extent  
415 threshold of 10 voxels with a height threshold of  $p < .05$  (uncorrected).

416

417 **3 Results**418 *3.1. Behavioral performance*

419       The RT results are presented in Fig. 3. The 2 (cue type)  $\times$  3 (cue-target  
420 validity) repeated-measures ANOVA for RT revealed a significant main effect  
421 of cue-target validity, indicating that RTs were shorter for valid cues  
422 compared with invalid and non-directional cues ( $F(2, 24) = 20.96, p < 0.05$ ).  
423 The main effect of cue type ( $F(1, 12) = 0.48, p > 0.1$ ) and the interaction  
424 between cue type and cue-target validity ( $F(2, 24) = 0.75, p > 0.1$ ) were not  
425 significant. The multiple comparisons for the main effect of cue-target

426 validity revealed that the RTs under the valid condition were shorter than  
427 were those under the invalid ( $t(24) = 5.89, p < 0.05$ ) and non-directional ( $t$   
428 ( $24) = 5.27, p < 0.05$ ) conditions. Non-parametric Wilcoxon signed-rank  
429 tests confirmed significant differences between valid cues compared with  
430 invalid and non-directional cues ( $Z > 3.10, p < 0.05$ ) as well the lack of  
431 significant differences between gaze and arrow cues under each validity  
432 condition ( $Z < 0.25, p > 0.1$ ). The results revealed that participants exhibit  
433 cueing effects of comparable magnitudes in response to both gaze and arrow  
434 cues.

438 3.2. MEG: commonality

439 The inverse reconstruction to compute cortical source activities from  
440 MEG signals was conducted in eight predefined regions of interest (the IOG,  
441 STS, IPL, and IFG in both hemispheres). We analyzed 3D  
442 source-reconstructed images in the MNI standard space of cortical source  
443 activity. The common activity associated with the effect of cue direction  
444 (directional vs. non-directional) across cue types (gaze and arrow) was  
445 tested using a conjunction analysis with interaction masking. The main  
446 effect of cue direction, contrasting directional and non-directional cues, was  
447 tested for each 50-ms time window. Within the 0–50, 50–100, 100–150, and

448 150–200 ms time windows, no significant activations were observed.  
 449 Significant activations were observed at 200–250 ms in the right STS region  
 450 ( $t(564) = 1.70$ ,  $p = 0.04$ ; Fig. 4), at 250–300 ms in the left IFG ( $t(564) = 2.44$ ,  
 451  $p = 0.007$ ), at 300–350 ms in the bilateral IFG (left:  $t(564) = 2.46$ ,  $p = 0.007$ ;  
 452 right  $t(564) = 1.77$ ,  $p = 0.038$ ) and the left STS ( $t(564) = 1.81$ ,  $p = 0.035$ ),  
 453 and at 350–400 ms in the left STS region ( $t(564) = 2.47$ ,  $p = 0.007$ ) and the  
 454 bilateral IFG (left:  $t(564) = 1.90$ ,  $p = 0.029$ ; right:  $t(564) = 1.86$ ,  $p = 0.035$ ).

455 \*\*\*\*\*

456 Figure 4

457 \*\*\*\*\*

458 Multiple regression analysis was performed to investigate the  
 459 relationships between MEG source activity (the contrasts between the  
 460 directional and non-directional conditions) and behavioral measures (RT  
 461 ratios between invalid and valid conditions). Significant positive  
 462 relationships were found at 200–250 ms with the left STS region ( $t(22) =$   
 463  $1.88$ ,  $p = 0.03$ ; Fig. 5) and the bilateral IFG (left:  $t(22) = 2.58$ ,  $p = 0.005$ ;  
 464 right:  $t(22) = 2.08$ ,  $p = 0.019$ ); at 250–300 ms with the right IOG ( $t(22) =$   
 465  $2.34$ ,  $p = 0.01$ ) and the left IFG ( $t(22) = 2.23$ ,  $p = 0.013$ ); at 300–350 ms with  
 466 the bilateral IOG (left:  $t(22) = 2.27$ ,  $p = 0.017$ ; right:  $t(22) = 2.17$ ,  $p = 0.015$ )  
 467 and the left IFG ( $t(22) = 1.79$ ,  $p = 0.037$ ); and at 350–400 ms with the  
 468 bilateral IOG (left:  $t(22) = 1.92$ ,  $p = 0.035$ ; right:  $t(22) = 2.78$ ,  $p = 0.005$ ).

481

482

The inverse reconstruction to compute cortical source activities from MEG signals was conducted in six predefined ROIs (the SPL, PCG, and MTG in both hemispheres). We analyzed the specific instances in which higher activity was more strongly associated with one stimulus type than with the other. Significant activations were observed only in the 350–400 ms time window. The SPL in both hemispheres was activated in response to directional arrow cues (right:  $t(564) = 1.82$ ,  $p = 0.034$ ; left:  $t(564) = 1.75$ ;  $p = 0.039$ , Fig.6), whereas the MTG in both hemispheres (right:  $t(564) = 3.45$ ,  $p < 0.001$ ; left:  $t(564) = 2.58$ ;  $p = 0.005$ ) and the left PCG ( $t(564) = 1.81$ ;  $p = 0.035$ ) was activated in response to directional gaze cues.

**4 Discussion**

487

488

489

490

491

The behavioral data from the present study demonstrate that participants localize cued targets more rapidly than they localize non-cued targets, irrespective of cue type. These results are consistent with previous findings indicating that both gaze (e.g., Friesen and Kingstone, 1998) and arrow (e.g., Tipples, 2002) cues automatically trigger attentional shifts. The

492 participants analyzed in this study exhibited cueing effects of comparable  
493 magnitudes in response to both gaze and arrow cues. This allowed for the  
494 investigation of the neural substrates underlying the common behavioral  
495 response of attentional shifts induced by gaze and arrow cues.

496         The MEG data from the present study revealed a common activation  
497 for directional versus non-directional gaze and arrows in the STS and IFG.  
498 These spatial patterns are consistent with previous fMRI studies that  
499 indicate that directional gaze and arrows activate widespread  
500 temporoparietal and frontal regions (Sato et al., 2009 and Tipper et al.,  
501 2008). These results are also in line with the theoretical proposal that a  
502 neural network, which includes the STS and IFG, is associated with the  
503 reorienting of attention (Corbetta and Shulman, 2002) and suggest that the  
504 STS and the IFG perform the psychological process common to the  
505 attentional shifts induced by directional gaze and arrows.

506         Moreover, these MEG data revealed commonalities in the temporal  
507 profiles of this neural activation. First, directional versus non-directional  
508 cues commonly activated the right STS region at 200–250 ms. A visual  
509 inspection of this component (Fig. 4) indicates that the peak of this  
510 component occurred during the 150–200-ms time window, which is in line  
511 with several previous EEG and MEG studies using facial stimuli (e.g.,  
512 Bentin et al., 1996; for a review, see Rossion and Jacques, 2008). The  
513 difference between cue directions at this component is also consistent with

514 several EEG and MEG studies reporting higher amplitude for this component  
515 in response to an averted than to a straight gaze (Puce et al., 2000; Sato et al.,  
516 2008 and Watanabe et al., 2001). Hietanen et al. (2008) found that, in the  
517 cueing paradigm, both directional gaze and arrows induce larger amplitudes  
518 in this component than do non-directional cues. A previous combined fMRI  
519 and ERP study also reported that the amplitude of this component was  
520 correlated with BOLD signals in face-related regions including the STS  
521 (Horovitz et al., 2004). This result is also consistent with data from  
522 single-unit recording studies in monkeys that found that a subset of cells in  
523 the STS codes the direction of another's attention regardless of the visual  
524 features (Jellema et al., 2000 and Perrett et al., 1992) and with neuroimaging  
525 studies in humans that found that the STS was activated in response to  
526 different social attention signals including gaze (Hoffman and Haxby, 2000)  
527 and gestures (Sato et al., 2009). Together with these data, the current results  
528 suggest that the activation of the right STS region at 200–250 ms is involved  
529 in extracting directional information, irrespective of cue type.

530       Subsequently, after 250 ms, the focus of activation moved to the left  
531 IFG. The activation of the IFG in these time windows has also been shown  
532 by previous MEG studies. Nishitani et al. (2004) found that the left IFG was  
533 active at around 250 ms when participants observed and imitated another's  
534 mouth action. Sato et al. (submitted) demonstrated that dynamic versus  
535 static facial expressions activate the right IFG at 300–350 ms. Based on

536 these findings, it would be reasonable to think that the information about cue  
537 direction processed by the right STS was transferred into the left IFG during  
538 this time window. It has been proposed that the STS and IFG are associated  
539 with the reorienting of attention by behaviorally relevant stimuli (Corbetta  
540 and Shulman, 2002). In our daily lives, the ability to react to the direction of  
541 gaze and arrows is highly relevant to the ability to effectively communicate  
542 with others (cf. Guzzon et al., 2010). Given that both factorial and  
543 regression analyses relate the overlapped left IFG activity to directional cues,  
544 this activation may be critical for attentional shifts induced by gaze and  
545 arrow cues.

546       The present findings also revealed the activation of the bilateral IFG  
547 and the left STS after 300 ms. Although the STS and IFG play an important  
548 role in orienting attention (e.g., Corbetta and Shulman, 2002), other studies  
549 have suggested that these brain regions are involved in various cognitive  
550 functions. For example, it has been proposed that the mirror neuron network,  
551 which includes the IFG and the STS, is employed in understanding the action  
552 intention of others (Rizzolatti et al., 2001). Previous fMRI studies suggest  
553 that the IFG and the STS play a role when inferring the intentions behind a  
554 symbolic gesture (Villarreal et al., 2012) and the animated motion of  
555 non-biological objects (Osaka et al., 2012 and Schultz et al., 2004).  
556 Behavioral studies also suggest that the inference of intention would be a  
557 critical component in attentional shifts induced by gaze and arrows. For

558 example, some studies have shown that biological and non-biological cues  
559 did not trigger an attentional shift when the model's intention was  
560 ambiguous (Teufel et al., 2010 and Wiese et al., 2012). Based on these  
561 findings, the left STS activation and the prolonged activity of the bilateral  
562 IFG might function as a system that sustains or suppresses attentional shifts  
563 depending on whether information about intention is extracted from the cue.

564       The regression analysis also revealed that the activation of the STS and  
565 the IFG were positively correlated with the degree of the attentional shifts  
566 induced by gaze and arrow cues. We also found a positive relationship  
567 between the later activation (~250 ms) of the bilateral occipital cortex and  
568 the cueing effect. Previous EEG studies have reported that gaze and arrow  
569 cues trigger the enhancement of subsequent visual processing at  
570 occipitotemporal sites (Hopf and Mangun, 2000 and Schuller and Rossion,  
571 2004). These findings suggest the possibility that the STS and the IFG send  
572 feedback signals to the visual cortex and enhance the visual processing of  
573 the subsequent target.

574       Spatial and temporal commonalities in the brain regions underlying the  
575 attentional shifts induced by gaze and arrows suggest that the human brain  
576 has incorporated the neural mechanisms for the processing of biological cues  
577 into those used for the processing of symbolic cues. Previous studies have  
578 shown that biological cues, including gaze, trigger attentional shifts even in  
579 macaque monkeys (Deaner and Platt, 2003). However, in addition to

580 biological cues, symbolic representations of directional information, such as  
581 arrows (Sato et al., 2010) and words (i.e., right and left; Vecera and Rizzo,  
582 2006), also trigger automatic attentional shifts in humans. Promising  
583 directions for further research include whether other attention-orienting cues  
584 (e.g., directional words) are also processed in the same manner and how  
585 spatial and temporal commonalities in the neural mechanisms underlying  
586 attentional shifts have developmentally and evolutionally emerged.

587       In contrast to our results showing common STS activation in response  
588 to gaze and arrow cues, some previous fMRI studies have reported different  
589 activation patterns in the STS in response to these cues (Hietanen et al. 2006  
590 and Kingstone et al., 2004). Kingstone et al. (2004) found stronger STS  
591 activation in response to gaze than to other cues. They presented cue stimuli  
592 that could be perceived as eyes or as cars based on an instruction. This  
593 finding does not exclude the engagement of the STS during processing of  
594 other directional cues because cars do not inherently indicate the location of  
595 objects. Hietanen et al. (2006) found that gaze cues did not induce STS  
596 activation. In contrast to other studies (Sato et al., 2009, Tipper et al., 2008  
597 and Kingstone et al., 2004), Hietanen et al. included no female participants.  
598 This may introduce ambiguity into the significance of STS activity in  
599 response to gaze cues, as women are more sensitive to the gaze of others  
600 than are men (see Frischen et al. (2007) for a review). In addition to these  
601 issues, these analyses differ from a methodological perspective. Previous

602 studies (Hietanen et al. 2006 and Kingstone et al., 2004) performed separate  
603 contrasts for each cue and tested the difference in brain activity between  
604 gaze and arrow cues, whereas we performed statistical conjunction analyses  
605 to investigate the commonality from a positive perspective. This difference  
606 may explain the inconsistent results among the studies.

607 In addition to these areas of commonality, we also found differences in  
608 brain activity in response to gaze and arrow cues at the 350–400-ms time  
609 window. The results revealed that the SPL in both hemispheres was activated  
610 in response to directional arrow cues, whereas the MTG in both hemispheres  
611 and the left PCG was activated in response to directional gaze cues. Previous  
612 fMRI studies also demonstrated that arrow cues specifically activated the  
613 SPL (Hietanen et al., 2006 and Sato et al., 2009). Corbetta and Shulman  
614 (2002) proposed that the dorsal attention networks, including the SPL, were  
615 involved in top-down attention control, whereas the ventral attention  
616 networks were associated with stimulus-driven attention orienting. Several  
617 studies have shown that arrow cues trigger attentional shifts only when  
618 participants intend to follow the direction of the cues (e.g., Posner, 1980).  
619 These findings suggest that differences in brain activity may appear during  
620 later time windows, reflecting the stronger top-down control of attention  
621 induced by arrow than by gaze cues.

622 Several limitations of the current study should be acknowledged. First,  
623 although the functional roles of the STS and the IFG at each time window

624 were discussed, the relationship between neural activation and the  
625 behavioral cueing effect addressed here was correlational rather than causal.  
626 The application of noninvasive transcranial stimulation methods could  
627 provide important information regarding whether the activation in specific  
628 brain regions in specific time windows is critical for automatic attention  
629 orienting by directional gaze and arrow cues. Second, this study did not find  
630 any activation of the IPL in response to directional gaze and arrow cues.  
631 This might relate to the fact that MEG has the disadvantage of being  
632 insensitive to deep or radially oriented sources (Dale and Sereno, 1993).  
633 Additional complementary methods with high spatial–temporal resolution  
634 (e.g., a combined EEG and fMRI study) would provide useful information  
635 concerning the neurocognitive mechanisms involved in attentional shifts  
636 induced by gaze and arrow cues. Third, some participants did not show  
637 reflexive attention orienting in response to gaze and arrow cues and were  
638 excluded from the MEG analysis. Several previous studies have shown that  
639 reflexive attention orienting clearly appeared at a shorter SOA (e.g.,  
640 Langton and Bruce, 1999). Although we selected a relatively longer SOA to  
641 record a clear MEG signal without contamination by response-related  
642 activities, a shorter SOA may be useful for inducing robust reflexive  
643 attention orienting and underlying brain activation. Fourth, this study  
644 focused on cue-related and not target-related activity. A recent fMRI study  
645 comparing invalidly and validly cued targets demonstrated that arrow but not

646 gaze cues recruited widely distributed brain regions including the STS, IPL,  
647 and IFG (Engell et al., 2010). Although eye movement and the  
648 response-related electromyogram to the peripherally presented target may  
649 contaminate the MEG signal, MEG would be useful for investigating the  
650 temporal characteristics of target-related activity in response to gaze and  
651 arrow cues.

652

## 653 **5 Conclusions**

654 The current study investigated the temporal dynamics of brain  
655 activation during attentional shifts induced by gaze and arrow cues. These  
656 findings demonstrate that both the STS and IFG are more activated in  
657 response to directional than non-directional gaze and arrow cues and that  
658 they exhibit a common temporal profile from 200–400 ms after cue onset.  
659 The regression analyses revealed that the activation of brain regions close to  
660 those specified in the factorial analysis (the STS and the IFG) and of the  
661 bilateral occipital cortex are positively correlated with the degree of the  
662 attentional shifts induced by gaze and arrow cues. We also found differences  
663 in brain activity in response to gaze and arrow cues at the 350–400-ms time  
664 window. The SPL in both hemispheres was activated in response to  
665 directional arrow cues, whereas the MTG in both hemispheres and the left  
666 PCG was activated in response to directional gaze cues. These results  
667 indicate commonalities and differences in the spatiotemporal neural

668 dynamics underlying the attentional shifts by gaze and arrow cues.

814 **Figure Legends**815 **Figure 1** Examples of gaze and arrow stimuli.

816

817 **Figure 2** Sequence of stimulus presentation under the invalid condition.

818

819 **Figure 3** Mean (with *SE*) reaction times to localize the target.

820

821 **Figure 4** Common brain activation in response to directional versus  
822 non-directional gaze and arrow cues in each time window. The height  
823 threshold of  $p < 0.05$  (uncorrected) with the extent threshold of 10 voxels.  
824 Waveforms represent source estimates in response to directional and  
825 non-directional gaze and arrow cues in the ROIs. Error bars show the *SE*.

826

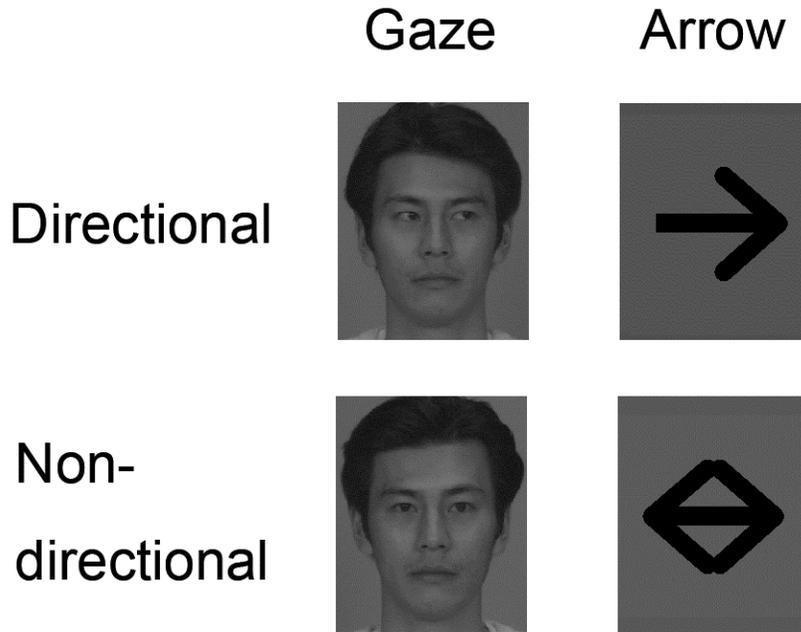

827 **Figure 5** Common brain regions showing a positive relationship between the  
828 cueing effect and the activation to directional versus non-directional gaze  
829 and arrow cues in each time window. The height threshold of  $p < 0.05$   
830 (uncorrected) with the extent threshold of 10 voxels. RT ratios between  
831 invalid and valid conditions were also calculated for each participant under  
832 gaze and arrow conditions and used as a measure of the cueing effect. The  
833 cueing effect is plotted against contrasts between the directional and  
834 non-directional conditions in the ROIs. Solid and broken lines represent  
835 linear regressions in gaze and arrow cues, respectively.

836

837 **Figure 6** The brain regions showing different activation in response to  
838 directional versus non-directional gaze and arrow cues at 350–400 ms. The  
839 height threshold is  $p < 0.05$  (uncorrected), and the extent threshold is 10  
840 voxels. Waveforms represent source estimates in response to directional and  
841 non-directional gaze and arrow cues in the ROIs. Error bars show the *SE*.
