Keywords: airway epithelial cells, air-liquid interface culture, mucociliary transport, hydrogen peroxide

Abstract

The effects of environmental pollutants on airway clearance have not been well elucidated. This study examined mucociliary transport using different sized-fluorescent particles on polarized human airway epithelial cells which were maintained in an air-liquid interface (ALI) culture system. The effects of hydrogen peroxide (H_2O_2) exposure on mucociliary transport were also investigated. The movement of fluorescent particles with diameters of 10–14 μm and 2.5–4.5 μm was observed by fluorescent microscopy as an index of the mucociliary transport. The mixture of the particles with two different sizes were propelled concentrically on the apical surface by the interaction of ciliary activity and mucus in the control condition, whereas H_2O_2 exposure for 24 h significantly inhibited the movement of the particles. The particle sizes did not affect their movement after the control or H_2O_2 exposure. These results suggest that particle tracking on polarized human airway epithelial cells is a useful experimental tool for the evaluation of the effect of environmental pollutants on mucociliary transport. In addition, reactive oxygen species may impair mucociliary transport, leading to the airway damage, and exacerbation of respiratory diseases.

1. Introduction

Airway epithelial cells are composed of a variety of cell types, including ciliated, goblet, and basal cells, and they function as the first barrier against inhaled xenobiotics (Tam et al. 2011). Goblet cells, in particular, synthesize and secrete mucin-rich mucus which traps the inhaled particles, viruses and bacteria, and then these xenobiotics are eliminated from the respiratory tract by mucociliary transport. The airway's surface liquid consists of two types of liquid where the upper layer is highly viscous and the lower is watery. The cilia are immersed in the watery layer with lower viscosity, which enables the cilia to beat (Smith et al. 2008; Cone et al. 2009). The overlying mucous layer is propelled by the penetration of cilia tips during beating.

In previous studies, airway epithelial cell lines such as A549, BEAS-2B and Calu3 have contributed to respiratory research. Polarized human airway epithelial cells have also been used as a respiratory model; they enable mucociliary transport (Bayam et al. 1998). Air-liquid interface (ALI) cultures are under development as a useful tool for analyses of airway epithelial cell function. For example, in an ALI culture, basal-lateral side of epithelial cells is immersed in culture medium and the apical side is exposed to humidified air with 5% CO₂. Not only the monolayer but also polarized epithelial cells have been introduced to ALI cultures (Seagrave et al. 2007; Huang et al. 2009; Stewart et al. 2012). These cultures mimic the construction of the airway and enable us to conduct *in vitro* studies under conditions that are close to *in vivo*

conditions. Accordingly, ALI cultures are one of the airway models that make evaluations of advanced function easier.

The impairment of mucociliary transport by environmental pollutants may cause or increase the risk of respiratory diseases such as asthma. Hydrogen peroxide (H_2O_2) is one of the major reactive oxygen species (ROS) known to induce oxidative stress, which leads subsequently to cellular damage in the airway. H_2O_2 is synthesized by exogenous or endogenous sources. In exogenous sources, H_2O_2 is produced through the bimolecular combination of HO_2 , which is produced primarily from the photolysis of O_3 [$\text{HO}_2 + \text{HO}_2 (+\text{H}_2\text{O}) \rightarrow \text{H}_2\text{O}_2 + \text{O}_2$] (Lee et al. 2000). Exogenous H_2O_2 stimulates cell surface molecules or is diffusible through cell membranes. Previous studies have suggested that H_2O_2 causes mucin synthesis via transactivation of epidermal growth factor receptor in mucoepidermoid carcinoma cells from human lungs (NCI-H292), and that H_2O_2 affects tracheobronchial mucosa in guinea pigs (Greiff et al. 1999; Takeyama et al. 2000). In addition, McDonald et al (1993) have demonstrated that exogenous H_2O_2 exposure induces DNA single-strand breaks in airway epithelial cells. In endogenous sources, H_2O_2 is produced from mitochondria as the site of energy generation, and is converted to the hydroxyl radical which is highly reactive and induces cell damage (Ryter et al. 2007). A large number of studies have suggested that environmental pollutants including diesel exhaust particles, polycyclic aromatic hydrocarbons, metal and sand dust induce oxidative stress in the airway (Dye et al. 1999; Marano et al. 2002; Kim et al. 2003;

Chiba et al. 2011). However, the effects of oxidative stress and/or environmental pollutants on airway clearance have not been established.

The aim of the present study was to investigate whether commercially available polarized human airway epithelial cells are useful for the analysis of mucociliary transport and for evaluation of the effects of oxidative stress and/or environmental pollutants on mucociliary transport. Accordingly, we measured the movement of fluorescent particles on human airway epithelial cells maintained in an ALI culture system as an index of mucociliary transport.

2. Materials and methods

2.1. Air-liquid interface (ALI) cultures

Human airway epithelial cells, differentiated in a polarized primary culture (MucilAir™, Epithelix Sarl, Geneva, Switzerland), were derived from bronchial biopsies of a healthy male donor (Caucasian) and were cultivated on micro-porous filter in cell culture inserts. They were provided by Iwaki, Ltd. (Tokyo, Japan) and maintained in an ALI culture system according to the manufacturer's instructions using MucilAir™ culture medium at 37°C in a humidified atmosphere of 5% CO₂. After cells were maintained for about 5 months, we used them for experiments.

2.2. Periodic acid-Schiff (PAS) and hematoxylin-eosin (HE) staining

To confirm the differentiation of human airway epithelial cells, the cells were fixed in 10% formalin and embedded in paraffin wax. Sections were cut at 5 μm and stained with haematoxylin and eosin (HE) or periodic acid-Schiff (PAS).

2.3. Experimental protocol

Each insert was added apically with 200 μL saline solution (0.9% NaCl, 1.25 mM CaCl₂, 10 mM HEPES) for 30 min in a CO₂ incubator 24 h prior to the experiments. This washing step allowed the removal of accumulated mucus and therefore minimized the risk of interference with the test. The following day, the cells were incubated for 1 min in 200 μL of saline solution (0.9% NaCl, 1.25 mM CaCl₂, 10 mM HEPES) as control or 500 μM H₂O₂ (diluted in saline solution) and, all of the apical surface were exposed by saline solution or H₂O₂. However, it has been reported that applying an excess volume of 0.9% NaCl for a long time on the apical surface of MucilAir™ results in increased interleukin (IL)-8 release (Huang and Caulfuty 2009), then the saline solution or H₂O₂ was removed to avoid IL-8 release. A mixture of particles with two different sizes was prepared by polystyrene particles with diameters of 10–14 μm and 2.5–4.5 μm at each concentration of 1000 $\mu\text{g}/\text{mL}$ (Spherotech, Lake Forest, IL, USA). Twenty μL (no toxic volume) of saline solution or H₂O₂ including fluorescent particles was applied at the apical surface. The inserts were incubated in a CO₂ incubator for 24 h, and the mucociliary transport was then evaluated by video-microscopy.

2.4. Video-microscopy analysis of mucociliary transport

The motion and migration rate of polystyrene particles with diameters of 10–14 μm and 2.5–4.5 μm were used as an index of mucociliary transport. The movement of the mixed particles was observed with a fluorescence microscope (Keyence, Osaka, Japan) equipped with 200 \times or 40 \times magnification. The data were recorded at two opposite points (areas 1 and 2) per individual culture insert for 20 sec (Fig. 1). The movement of particles with each diameter was expressed as the percentage of migration compared to that of particles with a diameter of 10–14 μm under control condition at area 1 using Image_Pro_Plus software (Media Cybernetics, Rockville, MD, USA). The migration rate was filtered by excluding data on the particles which were not recognized as reliable particles because of the short detection time.

3. Results

3.1. Morphological features of airway epithelial cells in ALI culture system

We confirmed the morphology of airway epithelial cells in ALI cultures. Fully differentiated epithelial cells including ciliated, goblet and basal cells were observed by HE staining (Fig. 2A). Goblet cells and mucus were identified more on the apical side than on the basal side by PAS staining (Fig. 2B).

3.2. Effects of H₂O₂ on mucociliary transport of airway epithelial cells in ALI culture system

When there were no fluorescent particles on the apical side of the airway epithelial cells, the beating of the cilia was observed as a flickering appearance, because of the frequency of the beating. The movement of cellular debris was seen to be in circles under 200× magnification (Movie 1). After removing the cellular debris by washing, we investigated the effect of H₂O₂ on the mucociliary transport of airway epithelial cells 24 h after the exposure. We obtained two opposite points per individual culture insert to evaluate the response to H₂O₂ exposure. The particles with a diameter of 2.5–4.5 μm exhibited cohesion/adhesion in part.

Overall, the mixed particles on the apical surface circulated concentrically by the interaction of ciliary activity and mucus in the control conditions (Movies 2 and 3 show the movement of particles with diameters of 10–14 μm and 2.5–4.5 μm under 40× magnification, respectively). The tracks of the particles also reflected mucociliary transport (Fig. 3A). However, H₂O₂ exposure for 24 h on the apical side significantly inhibited the movement of particles with two different sizes (Movies 4 and 5 show the movement of particles with diameters of 10–14 μm and 2.5–4.5 μm under 40× magnification, respectively). The particles left no track for 20 sec (Fig. 3B). It was not clear whether the particle sizes markedly affected the mean migration rate in the control condition, or the decrease in the rate in the H₂O₂-exposed condition (Table 1).

4. Discussion

Human airway epithelial cells (Mucil Air™) in ALI culture system were confirmed as fully differentiated epithelial cells by HE and PAS staining. We examined mucociliary transport using fluorescent particles with different sizes on the polarized airway epithelial cells in ALI culture. We also investigated the effects of H₂O₂ exposure on mucociliary transport. It was possible to evaluate mucociliary transport by measuring the tracks of the fluorescent particles. Moreover, mucociliary transport was inhibited by H₂O₂ exposure.

Airway epithelial cells are composed of a variety of cell types including ciliated, goblet, and basal cells, and their cell population was identified in the MucilAir™. Ciliated and goblet cells were found on the surface of the epithelial cells (Figs. 2A, B). Mucociliary transport under no fluorescent particles conditions was confirmed by the movement of cellular debris, which was the result of cooperation with ciliated cells and mucous from goblet cells (Movie 1). In the human body, normal mucociliary transport is highly directional toward the pharynx. However, in circular horizontal culture, previous studies have found that the mucus motion is in a rotational, hurricane-like, pattern (Matsui et al. 1998; Oldenburg et al. 2012). The results of the present study were consistent with these reports. Therefore, this cellular model was used as fully differentiated human airway epithelial cells.

There are some assessment techniques for mucociliary transport using ciliary beat

frequency (CBF) quantified by video record, radioactive tracer and fluorescent particles (Perdersen et al. 1990; Sears et al. 2011; Kunimoto et al. 2012). On the basis of these techniques, previous experimental reports have indicated that environmental pollutants including cigarette smoke, sulphur dioxide, nitrogen dioxide, ozone, diesel exhaust particles, and formaldehyde decrease ciliary activity (Hastie et al. 1990; Knorst et al. 1994; Helleday et al. 1995; Bayram et al. 1998 a, b; Gosepath et al. 2000; Simet et al. 2010). It has also been shown that H₂O₂ causes decline in ciliary activity in rats and sheep (Burman and Martin, 1986; Kobayashi et al. 1992). Scanning electron microscopy has revealed that the ciliated cells are severely damaged and epithelial basal cells are poorly connected in guinea-pigs exposed to H₂O₂ (Greiff et al. 1999). In the present study, we successfully applied a method to track fluorescent particles for the evaluation of mucociliary transport using polarized human airway epithelial cells, and our observations confirmed that H₂O₂ decreased the movement of particles on the cells, which may follow the inhibition of ciliary activity or mucous movement. Accordingly, the present results show that these tools, that is, polarized human airway epithelial cells and fluorescent particles under fluorescent detection, are very useful and easy to apply for evaluations of mucociliary transport and respiratory physiology, because Mucil Air™ is commercially available and a method to track fluorescent particles is non-radioactive assay. Moreover, the present results are consistent with those of previous studies and support that ROS such as H₂O₂ in the ambient atmosphere affects mucociliary transport.

Other studies have found that exposure to cigarette smoke and ozone increases or does not change mucociliary transport (Gerrity et al. 1993; Zhou et al. 2009). Environmental pollutants may thus have different effects on mucociliary transport depending on the conditions. Alterations of mucociliary transport may be determined by various factors such as species, types of cells and xenobiotics, the number of ciliated cells, the morphology of cilia, the ciliary beating pattern, the quantity and viscoelastic properties of mucus, and experimental conditions such as the exposed concentration and its duration. Accordingly, investigations that focus on each factor may be needed to identify the mechanisms by which mucociliary transport is inhibited by exposure to environmental pollutants.

It has been thought that in nasal breathing, particles with a diameter larger than 10 μm are deposited in the oropharynx and nasal cavity, and that those with a diameter smaller than 10 μm are deposited in central airways, bronchi and alveoli. However, in mouth breathing, particles with a diameter larger than 10 μm can reach bronchi (Heyder et al. 1986; Fernández and Casan 2012). We used fluorescent polystyrene particles with diameters of 10–14 μm and 2.5–4.5 μm , which can be deposited in the lower respiratory tract. Using tracheal tubes from the chicken embryos, Henning et al. (2010) have suggested that the clearance rates of various-sized polystyrene particles (0.05, 0.1, 1, and 6 μm) do not differ, whereas the material properties and the related particle surface chemistry significantly influence mucociliary transport. Snipes et al. (1984) have indicated that particles larger than 7 μm are retained after

deposition in the pulmonary region of the respiratory tract of dogs instilled with a mixture of 3-, 7-, and 13- μm particles. In the present study, polystyrene particles larger than 10 μm were tested as large particles, and they were mixed with the same polystyrene particles with 2.5–4.5 μm as small particles. The particle sizes did not affect the movement of particles in the control or the H_2O_2 exposure, although polystyrene particles themselves may suppress cellular activities. The difference in particle sizes may not have contributed to the movement of particles in the present experimental conditions or in the circular horizontal culture. Further investigations are needed to understand the effect of differences in particle sizes on mucociliary transport.

5. Conclusion

It may be useful to evaluate mucociliary transport by measuring the tracks of fluorescent particles on commercially available polarized human airway epithelial cells using ALI cultures. Exposure of cells to H_2O_2 could decrease mucociliary transport. Dysfunction of mucociliary transport induced by oxidative stress and/or environmental pollutants impair airway clearance. Subsequently, inhaled xenobiotics may easily contact with the cells of the respiratory and immune systems such as epithelial and dendritic cells, leading to the induction and/or exacerbation of respiratory diseases. Further investigations with statistical analysis are needed to evaluate mucociliary transport.
