Department of Physics, Kyoto University, Kyoto 606-8502, Japan (Received 26 November 2015; revised manuscript received 23 January 2016; published 29 February 2016)

Isovector and isoscalar dipole excitations in ⁹Be and ¹⁰Be are investigated in the framework of antisymmetrized molecular dynamics, in which angular-momentum and parity projections are performed. In the present method, 1p-1h excitation modes built on the ground state and a large amplitude α -cluster mode are taken into account. The isovector giant dipole resonance (GDR) in E > 20 MeV shows the two-peak structure, which is understood from the dipole excitation in the 2α core part with the prolate deformation. Because of valence neutron modes against the 2α core, low-energy E1 resonances appear in E < 20 MeV, exhausting about 20% of the Thomas-Reiche-Kuhn sum rule and 10% of the calculated energy-weighted sum. The dipole resonance at $E \sim 15$ MeV in ¹⁰Be can be interpreted as the parity partner of the ground state having a ⁶He + α structure and has remarkable E1 strength because of the coherent contribution of two valence neutrons. The isoscalar dipole strength for some low-energy resonances is significantly enhanced by the coupling with the α -cluster mode. For the E1 strength of ⁹Be, the calculation overestimates the energy-weighted sum (EWS) in the low-energy (E < 20 MeV) and GDR (20 < E < 50 MeV) regions by a factor of 1.6 and underestimates the width of the GDR, whereas it reasonably describes the GDR energy and also the ratio of the EWS in the low-energy region to that of the GDR region.

I. INTRODUCTION

In neutron-rich nuclei, various exotic phenomena appear because of excess neutrons. One of the current issues concerning exotic excitation modes in neutron-rich nuclei is lowenergy dipole excitations [1–77]. For stable nuclei, isovector giant dipole resonances (GDRs) have been systematically observed in various nuclei by measurements of photonuclear cross sections (for example, see Ref. [78] and references therein). The GDR is understood as an opposite oscillation between protons and neutrons and microscopically described by coherent 1p-1h excitations. Peak structure of the strength function of the GDR has been often discussed in relation to nuclear deformation. In neutron-rich nuclei, low-energy dipole resonances have been suggested to appear because of excess neutron motion against a core. The so-called soft dipole resonance, which is the enhanced E1 strength observed in the extremely low-energy ($E \leq 2-3$ MeV) region in neutron halo nuclei such as ⁶He and ¹¹Li, has been intensively studied by experimental and theoretical groups and often discussed in relation to the two-neutron correlation [1-8,13-30]. More generally the low-energy E1 strength typically in the $5 \le E \le$ 15 MeV region is predicted in various nuclei in a wide mass region, and the one decoupled from the GDR is called the pigmy dipole resonance. The role of excess neutrons and the collectivity of these low-energy dipole excitations are topics of interest in theoretical studies. The low-energy E1 strength has been also discussed in relation to neutron skin thickness and the density dependence of the symmetry energy, though their correlation is under debate [46,48,60–63,72,77].

The experimental measurements of the low-energy E1 strength in ⁹Be by photodisintegration have been performed mainly for astrophysical interests [79–83]. In recent years, precise data of the E1 strength for low-lying positive-parity states of ⁹Be have been reported [83]. Moreover, the recently measured photodisintegration cross sections of ⁹Be indicate

the significant low-energy E1 strength around E = 10 MeV exhausting about 10% of the Thomas-Reiche-Kuhn (TRK) sum rule [84], consistent with the bremsstrahlung data [81]. The experimental data of the E1 strength of ⁹Be are available in a wide energy region from low energy to high energy: the E1 strength for the positive-parity states in $E \leq 5$ MeV [83], the significant E1 strength around E = 10 MeV [81,84], and the E1 strength in E > 20 MeV for the GDR [85].

Our aim is to investigate isovector and isoscalar dipole strengths in ⁹Be and ¹⁰Be to understand the low-energy dipole modes. I try to clarify the role of excess neutrons and the decoupling mechanism of the low-energy dipole modes from the GDR. The low-lying states of ⁹Be are understood by $2\alpha + n$ cluster structures as discussed in cluster models [86-90]. The photodisintegration cross sections in the very low-energy region of ⁹Be have been theoretically investigated by two-body (⁸Be + n) and three-body $(2\alpha + n)$ cluster models with continuum states [91–97]. However, such cluster models are not able to describe the high-energy dipole strength of the GDR, to which coherent 1p-1h excitations may contribute. To investigate the pygmy and giant dipole resonances in general nuclei, shell model and mean-field approaches were applied. The former may not be suitable for such largely deformed nuclei as Be isotopes having cluster structures. The latter is usually based on the random phase approximation (RPA) with and without continuum. Although the RPA calculation is successful for a variety of collective excitations in heavy mass nuclei, it is a small amplitude approximation neglecting large amplitude motion. Moreover, in most current mean-field approaches, the RPA calculation is based on a parity-symmetric mean field in a strong coupling picture without the angular-momentum and parity projections, and the coupling of single-particle excitations in the mean field with rotation and parity transformation is not taken into account microscopically.

To take into account the coherent 1p-1h excitations and the large amplitude cluster mode as well as the angularmomentum and parity projections, we develop a method of antisymmetrized molecular dynamics (AMD) [98-103]. The time-dependent AMD, which was originally developed for study of heavy-ion reactions [98,99], was applied to investigate E1 and monopole excitations [39,104]. However, in the time-dependent AMD approach, the angular-momentum and parity projections are not performed, and, therefore, ground state structures and the coupling of single-particle excitations with the rotational motion are not sufficiently described. Instead of the time-dependent AMD, we superpose the angular-momentum and parity-projected wave functions of various configurations including the 1p-1h and cluster excitations. We first perform the variation after the angularmomentum and parity projections in the AMD framework (AMD+VAP) [105-107] to obtain the ground state wave function. Then we describe small amplitude motions by taking into account 1p-1h excitations on the obtained ground state wave function with the shifted basis AMD method as done in Ref. [108] for monopole excitations of ¹⁶O. To take into account the large amplitude cluster motion, we combine the generator coordinate method (GCM) with the shifted basis AMD by superposing 5,6 He + α cluster wave functions. The angular-momentum and parity projections are performed in the present framework. Applying the present method, I investigate the dipole transitions ${}^{8}Be(0^{+}_{1}) \rightarrow {}^{8}Be(1^{-}), {}^{9}Be(3/2^{-}_{1}) \rightarrow$ ${}^{9}\text{Be}(1/2^+, 3/2^+, 5/2^+)$, and ${}^{10}\text{Be}(0^+_1) \rightarrow {}^{10}\text{Be}(1^-)$.

This paper is organized as follows. The present method of AMD is formulated in Sec. II, and Sec. IV discusses the ground state structures and the E1 and isoscalar dipole (ISD) excitations in Be isotopes. The paper concludes with a summary in Sec. V.

II. FORMULATION OF AMD FOR DIPOLE EXCITATIONS

I apply the AMD+VAP method to obtain A-nucleon wave functions for the ground states of ⁸Be, ⁹Be, and ¹⁰Be. To investigate dipole excitations, I use the shifted basis AMD to describe the 1p-1h excitation modes built on the ground state. I also perform the α -cluster GCM calculation combined with the shifted basis AMD to see how the α -cluster mode affects the dipole excitations. In this section, I explain the formulation of the AMD+VAP, the shifted basis AMD, and the α -cluster GCM calculations and also describe the definition of the dipole strengths.

A. AMD wave function

An AMD wave function is given by a Slater determinant,

$$\Phi_{\text{AMD}}(\mathbf{Z}) = \frac{1}{\sqrt{A!}} \mathcal{A}\{\varphi_1, \varphi_2, \dots, \varphi_A\},\tag{1}$$

where A is the antisymmetrizer. The *i*th single-particle wave function φ_i is written by a product of spatial, spin, and isospin wave functions as

$$\varphi_i = \phi_{X_i} \chi_i \tau_i, \tag{2}$$

$$\phi_{\boldsymbol{X}_i}(\boldsymbol{r}_j) = \left(\frac{2\nu}{\pi}\right)^{4/3} \exp\{-\nu(\boldsymbol{r}_j - \boldsymbol{X}_i)^2\},\tag{3}$$

$$\chi_i = \left(\frac{1}{2} + \xi_i\right)\chi_{\uparrow} + \left(\frac{1}{2} - \xi_i\right)\chi_{\downarrow}, \qquad (4)$$

where ϕ_{X_i} and χ_i are the spatial and spin functions, respectively, and τ_i is the isospin function fixed to be up (proton) or down (neutron). The width parameter ν is fixed to be the optimized value for each nucleus. To separate the center-of-mass motion from the total wave function $\Phi_{AMD}(Z)$, the following condition should be satisfied:

$$\frac{1}{A} \sum_{i=1,\dots,A} X_i = 0.$$
 (5)

In the present calculation, I keep this condition and exactly remove the contribution of the center-of-mass motion.

Accordingly, an AMD wave function is expressed by a set of variational parameters, $Z \equiv \{X_1, \ldots, X_A, \xi_1, \ldots, \xi_A\}$, which specifies centroids of single-nucleon Gaussian wave packets and spin orientations for all nucleons. In the AMD framework, the existence of clusters is not assumed *a priori* because Gaussian centroids, X_1, \ldots, X_A , of all single-nucleon wave packets are independently treated as variational parameters. Nevertheless, a multicenter cluster wave function can be described by the AMD wave function with the corresponding configuration of Gaussian centroids. It should be noted that the AMD wave function is similar to the wave function used in fermionic molecular dynamics calculations [109,110].

B. AMD + VAP

In the AMD+VAP method, the parameters $\mathbf{Z} = \{X_1, X_2, \dots, X_A, \xi_1, \xi_2, \dots, \xi_A\}$ in the AMD wave function are determined by the energy variation after the angular-momentum and parity projections (VAP). It means that X_i and ξ_i for the lowest J^{π} state are determined so as to minimize the energy expectation value of the Hamiltonian for the J^{π} -projected AMD wave function:

$$\frac{\delta}{\delta X_i} \frac{\langle \Phi | H | \Phi \rangle}{\langle \Phi | \Phi \rangle} = 0, \tag{6}$$

$$\frac{\delta}{\delta\xi_i} \frac{\langle \Phi | H | \Phi \rangle}{\langle \Phi | \Phi \rangle} = 0, \tag{7}$$

$$\Phi = P_{MK}^{J\pi} \Phi_{\text{AMD}}(\mathbf{Z}), \tag{8}$$

where $P_{MK}^{J\pi}$ is the angular-momentum and parity projection operator. After the VAP calculation, the optimized parameters $Z_{VAP}^{J\pi}$ for the lowest J^{π} state are obtained. For the ground state, the VAP with $J^{\pi} = 0^+$ and K = 0 is performed for ⁸Be and ¹⁰Be, and that with $J^{\pi} = 3/2^-$ and K = 3/2 is done for ⁹Be. I denote the parameters $Z_{VAP}^{J\pi}$ obtained by the VAP for the ground state as $Z^0 = \{X_1^0, \ldots, \xi_1^0, \ldots\}$.

C. Shifted AMD

To take into account 1p-1h excitations, I consider the small variation of single-particle wave functions in the ground state wave function $\Phi_{AMD}(\mathbf{Z}^0)$ by shifting the position of the Gaussian centroid of the *i*th single-particle wave function,

 $X_i^0 \to X_i^0 + \epsilon e_{\sigma}$, where ϵ is a small constant and e_{σ} is a unit vector with the label σ . In the present calculation, e_1, \ldots, e_8 for eight directions are adopted to obtain the approximately converged result for the *E*1 and ISD strengths. Details of the adopted unit vectors e_{σ} ($\sigma = 1, \ldots, 8$) are described in Sec. IV. For the spin part, I consider the spin-nonflip single-particle state χ_i and the spin-flip state $\bar{\chi}_i$ ($\langle \bar{\chi}_i | \chi_i \rangle = 0$),

$$\bar{\chi}_i = \left(\frac{1}{2} + \bar{\xi}_i\right) \chi_{\uparrow} + \left(\frac{1}{2} - \bar{\xi}_i\right) \chi_{\downarrow},\tag{9}$$

where $\bar{\xi}_i = -1/4\xi_i^*$. For all single-particle wave functions, I consider spin-nonflip and spin-flip states shifted to eight directions independently and prepare 16A AMD wave functions, $\Phi_{AMD}(\mathbf{Z}_{nonflip}^0(i,\sigma))$ and $\Phi_{AMD}(\mathbf{Z}_{flip}^0(i,\sigma))$, with the shifted parameters

$$Z^{0}_{\text{nonflip}}(i,\sigma) \equiv \left\{ X^{0'}_{1}, \dots, X^{0'}_{i} + \epsilon e_{\sigma}, \dots, X^{0'}_{A}, \xi^{0}_{1}, \dots, \xi^{0}_{i}, \dots, \xi^{0}_{A} \right\}, \quad (10)$$
$$Z^{0}_{\text{flin}}(i,\sigma) \equiv \left\{ X^{0'}_{1}, \dots, X^{0'}_{i} \right\}$$

$$\begin{aligned} \stackrel{\text{offip}}{\underset{\text{fip}}{\text{fip}}}(i,\sigma) &\equiv \left\{ \boldsymbol{X}_{1}^{0}, \dots, \boldsymbol{X}_{i}^{0} \right. \\ &+ \epsilon \boldsymbol{e}_{\sigma}, \dots, \boldsymbol{X}_{A}^{0'}, \boldsymbol{\xi}_{1}^{0}, \dots, \boldsymbol{\bar{\xi}}_{i}^{0}, \dots, \boldsymbol{\bar{\xi}}_{A}^{0} \right\}. \end{aligned}$$
(11)

Here $X_j^{0'}$ is chosen to be $X_j^{0'} = X_j^0 - \epsilon e_{\sigma}/(A-1)$ to take into account the recoil effect so that the center-of-mass motion is separated exactly. Those shifted basis AMD wave functions $\Phi_{AMD}(\mathbf{Z}_{(non)flip}^0(i,\sigma))$ and the original wave function $\Phi_{AMD}(\mathbf{Z}^0)$ are superposed to obtain the final wave functions for the ground and excited states,

$$\Psi_{\text{Be}(J_{k}^{\pi})}^{\text{sAMD}} = \sum_{K} c_{0}(J_{k}^{\pi}; K) P_{MK}^{J\pi} \Phi_{\text{AMD}}(\mathbf{Z}^{0}) + \sum_{i=1,...,A} \sum_{\sigma} \sum_{K} c_{1}(J_{k}^{\pi}; i, \sigma, K) P_{MK}^{J\pi} \Phi_{\text{AMD}}(\mathbf{Z}_{\text{nonflip}}^{0}(i, \sigma)) + \sum_{i=1,...,A} \sum_{\sigma} \sum_{K} c_{2}(J_{k}^{\pi}; i, \sigma, K) P_{MK}^{J\pi} \Phi_{\text{AMD}}(\mathbf{Z}_{\text{flip}}^{0}(i, \sigma)),$$

$$(12)$$

where the coefficients c_0 , c_1 , and c_2 are determined by diagonalization of the norm and Hamiltonian matrices. I call this method the "shifted basis AMD" (sAMD). The spin-nonflip version of the sAMD was applied to investigate monopole excitations of ¹⁶O in Ref. [108].

I choose a small enough value of the spatial shift ϵ , typically $\epsilon = 0.1$ fm, so as to obtain ϵ -independent results. The model space of the sAMD contains the 1p-1h excitations that are written by a small shift of a single-nucleon Gaussian wave function of the ground state wave function. In the intrinsic frame before the angular-momentum and parity projections, the ground state AMD wave function is expressed by a Slater determinant, and, therefore, the sAMD method corresponds to the RPA in the restricted model space of the linear combination of shifted Gaussian wave functions. However, since the projected states are superposed in the sAMD, the coupling of the 1p-1h excitations with the rotation and parity transformation is properly taken into account. Therefore, the

sAMD contains, in principle, higher correlations beyond the RPA in mean-field approximation.

It is clear from the Taylor expansion of a Gaussian that the shift $X_i \rightarrow X_i + \epsilon e_{\sigma}$ of the Gaussian wave packet can be expressed by a linear combination of harmonic oscillator (HO) orbits around X_i ,

$$\phi_{X_i+\epsilon e_{\sigma}} \propto \sum_{k=0}^{\infty} \frac{1}{k!} (-2\epsilon)^k (\boldsymbol{r} \cdot \boldsymbol{e}_{\sigma})^k \phi_{X_i}.$$
(13)

In terms of the HO orbits around X_i , the $O(\epsilon^0)$, $O(\epsilon^1)$, $O(\epsilon^2)$, and $O(\epsilon^3)$ terms cover 0s, $\{0p\}$, $\{1s, 0d\}$, and $\{1p, 0f\}$ orbits, respectively. The $O(\epsilon)$ term contains $r\phi_{X_i}$ excited by the E1 operator, whereas the $O(\epsilon^3)$ term contains $r^2 \mathbf{r} \phi_{X_i}$ configurations excited by the ISD operator. Therefore, in the small ϵ limit, the number of independent vectors e_{σ} necessary to exactly cover the excited configurations $r\phi_{X_i}$ for E1 is three, and that $(r^2 r \phi_{X_i})$ for ISD is 19 = 3 + 6 + 10. Thus, the model space of the shifted Gaussian for each single-particle wave function is rather trivial; however, the model space of the sAMD is not trivial because of the recoil effect. Moreover, it is expected that, in the sAMD framework, the configurations excited by the E1 and ISD operators should be efficiently covered by a smaller number of e_{σ} because of the effects of the antisymmetrization and the angular-momentum and parity projections. To save the computational cost, I checked the convergence of the dipole strengths for the number of e_{σ} and chose a set of eight vectors as mentioned previously. Note that, when the recoil effect is omitted, the sAMD can be regarded as an extended AMD method, in which higher HO orbits are described as well as the default 0s orbit at X_i for the *i*th single-particle wave function. In the particular case of $\sigma = x, y, z$, it can be called the "*p*-wave AMD."

D. α-cluster GCM

In the ground state wave functions obtained by the AMD+VAP for ⁸Be, ⁹Be, and ¹⁰Be, an α cluster is formed even though any clusters are not *a priori* assumed in the framework. Consequently, Gaussian centroids X_i^0 for two protons and two neutrons are located at almost the same position. The intercluster motion of ⁵He + α and ⁶He + α structures in ⁹Be and ¹⁰Be can be excited by the dipole operators. To take into account the large amplitude α -cluster mode, we perform the α -cluster GCM (α GCM) calculation with respect to the intercluster distance. For simplicity, we label four nucleons composing the α cluster as $i = 1, \ldots, 4$ and other nucleons as $i = 5, \ldots, A$. The center-of-mass position of the α cluster is localized around $R_{\alpha} = \frac{1}{4}$ Re[$X_1^0 + X_2^0 + X_3^0 + X_4^0$]. The intercluster distance D_{α} is written as

$$D_{\alpha} \equiv \left| \text{Re} \left[\frac{1}{4} \sum_{i=1,\dots,4} X_{i}^{0} - \frac{1}{A-4} \sum_{i=5,\dots,A} X_{i}^{0} \right] \right| = \frac{A}{A-4} R_{\alpha}$$
(14)

with $R_{\alpha} \equiv |\mathbf{R}_{\alpha}|$. To perform the α GCM calculation based on the ground state wave function $\Phi_{\text{AMD}}(\mathbf{Z}^0)$, I changed the intercluster distance $D_{\alpha} \rightarrow D_{\alpha} + \Delta D$ by shifting positions of single-nucleon Gaussian centroids $X_i^0 \to X_{i,D_\alpha}^0(\Delta D)$ by hand as

$$\boldsymbol{X}_{i,D_{\alpha}}^{0}(\Delta D) = \boldsymbol{X}_{i}^{0} + \frac{A-4}{A} \Delta D \, \hat{\boldsymbol{R}}_{\alpha} \quad (i \leq 4), \quad (15)$$

$$\boldsymbol{X}_{i,D_{\alpha}}^{0}(\Delta D) = \boldsymbol{X}_{i}^{0} - \frac{4}{A}\Delta D\,\hat{\boldsymbol{R}}_{\alpha} \quad (i > 4), \qquad (16)$$

and superposing the wave functions with different ΔD values. I combined the α GCM with the sAMD and express the total wave function as

$$\begin{split} \Psi_{\text{Be}(J_{k}^{\pi})}^{\text{sAMD}+\alpha} \text{GCM} \\ &= \sum_{K} c_{0} \left(J_{k}^{\pi}; K \right) P_{MK}^{J\pi} \Phi_{\text{AMD}} (\mathbf{Z}^{0}) \\ &+ \sum_{i=1,\dots,A} \sum_{\sigma} \sum_{K} c_{1} \left(J_{k}^{\pi}; i, \sigma, K \right) P_{MK}^{J\pi} \Phi_{\text{AMD}} \left(\mathbf{Z}_{\text{nonflip}}^{0}(i, \sigma) \right) \\ &+ \sum_{i=1,\dots,A} \sum_{\sigma} \sum_{K} c_{2} \left(J_{k}^{\pi}; i, \sigma, K \right) P_{MK}^{J\pi} \Phi_{\text{AMD}} \left(\mathbf{Z}_{\text{flip}}^{0}(i, \sigma) \right) \\ &+ \sum_{\Delta D} \sum_{K} c_{3} \left(J_{k}^{\pi}; \Delta D, K \right) P_{MK}^{J\pi} \Phi_{\text{AMD}} \left(\mathbf{Z}_{D_{\alpha}}^{0}(\Delta D) \right), \quad (17) \end{split}$$

where $Z_{D_{\alpha}}^{0}(\Delta D) \equiv \{X_{1,D_{\alpha}}^{0}(\Delta D), \dots, X_{A,D_{\alpha}}^{0}(\Delta D), \xi_{1}, \dots, \xi_{A}\}$. The coefficients are determined by diagonalization of the norm and Hamiltonian matrices.

III. ISOVECTOR AND ISOSCALAR DIPOLE TRANSITIONS

The *E*1 operator $\mathcal{M}(E1; \mu)$ is given by the isovector dipole operator as

$$\mathcal{M}(E1;\mu) = \frac{N}{A} \sum_{i}^{\text{proton}} r_i Y^1_{\mu}(\hat{\boldsymbol{r}}_i) - \frac{Z}{A} \sum_{i}^{\text{neutron}} r_i Y^1_{\mu}(\hat{\boldsymbol{r}}_i).$$
(18)

The ISD operator $\mathcal{M}(IS1; \mu)$ is defined as

$$\mathcal{M}(\text{IS1};\mu) = \sum_{i} r_i^3 Y_{\mu}^1(\hat{\boldsymbol{r}}_i), \qquad (19)$$

which excites the compressive dipole mode. The *E*1 and ISD strengths for the transition g.s. $\rightarrow J_k$ are given by the matrix elements of the dipole operators as

$$B(E1; g.s. \to J_k) = \frac{1}{2I_{g.s.} + 1} |\langle J_k || \mathcal{M}(E1) || g.s. \rangle|^2, \quad (20)$$

$$B(\text{IS1}; \text{g.s.} \to J_k) = \frac{1}{2I_{\text{g.s.}} + 1} |\langle J_k || \mathcal{M}(\text{IS1}) || \text{g.s.} \rangle|^2, \quad (21)$$

where $I_{g.s.}$ is the ground state angular momentum. The energyweighted sum (EWS) of the *E*1 and ISD strengths is defined as

$$S(E1) \equiv \sum_{J_k} E_{J_k} B(E1; \text{g.s.} \to J_k), \qquad (22)$$

$$S(\text{IS1}) \equiv \sum_{J_k} E_{J_k} B(\text{IS1}; \text{g.s.} \to J_k), \qquad (23)$$

where E_{J_k} is the energy of the J_k state. If the interaction commutes with the E1 operator, S(E1) is identical to the TRK sum rule:

$$S(\text{TRK}) \equiv \frac{9\hbar^2}{8\pi m} \frac{NZ}{A}.$$
 (24)

Since the nuclear interaction does not commute with the E1 operator, S(E1) is usually enhanced from S(TRK).

In the present framework, all excited states are discrete states without escaping widths because the outgoing condition in the asymptotic region is not taken into account. I calculate the E1 and ISD strengths for discrete states and smear the strengths with a Gaussian by hand to obtain dipole strength functions as

$$\frac{dB(E1)}{dE} = \sum_{J} \sum_{k} \frac{\sqrt{\pi}}{\gamma} e^{-\frac{(E-E_{J_k})^2}{\gamma^2}} B(E1; \text{g.s.} \to J_k), \quad (25)$$

$$\frac{dB(\text{IS1})}{dE} = \sum_{J} \sum_{k} \frac{\sqrt{\pi}}{\gamma} e^{-\frac{(E-E_{J_k})^2}{\gamma^2}} B(\text{IS1}; \text{g.s.} \to J_k), \quad (26)$$

where γ is the smearing width. The photonuclear cross section is dominated by *E*1 transitions and related to the *E*1 strength function as

$$\sigma(E) = \frac{16\pi^3}{9} \frac{e^2}{\hbar c} E \frac{dB(E1)}{dE}.$$
 (27)

IV. RESULTS

A. Effective nuclear interactions

I used an effective nuclear interaction consisting of the central force of the MV1 force [111] and the spin-orbit force of the G3RS force [112,113] and the Coulomb force. The MV1 force is given by a two-range Gaussian two-body term and a zero-range three-body term. The G3RS spin-orbit force is a two-range Gaussian force. The Bartlett, Heisenberg, and Majorana parameters for case 1 of the MV1 force are b = h = 0 and m = 0.62, and the strengths of the G3RS spin-orbit force are $u_1 = -u_{11} \equiv u_{1s} = 3000$ MeV. These interaction parameters are the same as those used in Refs. [105–107], in which the AMD+VAP calculation describes well the properties of the ground and excited states of ¹⁰Be and ¹²C.

B. Ground states

I performed the AMD+VAP calculation to obtain the ground state wave functions for ${}^{8}Be(0^{+}_{1})$, ${}^{9}Be(3/2^{-}_{1})$, and ${}^{10}Be(0^{+}_{1})$. For comparison, I also applied it to ${}^{4}He(0^{+}_{1})$. The width parameter was chosen to be $\nu = 0.20$ fm⁻² for ${}^{8}Be$ and ${}^{9}Be$, $\nu = 0.19$ fm⁻² for ${}^{10}Be$, and $\nu = 0.21$ fm⁻² for ${}^{4}He$ to minimize the ground state energy. Figure 1(a) shows the intrinsic density distribution of the obtained wave functions $\Phi_{AMD}(Z^{0})$ for the ground states of Be. As seen in the density, the $\alpha + \alpha$, ${}^{5}He + \alpha$, and ${}^{6}He + \alpha$ cluster structures are developed in ${}^{8}Be$, ${}^{9}Be$, and ${}^{10}Be$, respectively. Considering that the ${}^{5}He$ and ${}^{6}He$ clusters have $\alpha + n$ and $\alpha + 2n$ structures, the ground states of ${}^{9}Be$ and ${}^{10}Be$ are regarded as the 2α cluster core with valence neutrons, $2\alpha + n$ and $2\alpha + 2n$, in which the valence neutrons are localized around one of the 2α .

FIG. 1. Density distribution of the intrinsic wave functions of the ground states of ⁸Be, ⁹Be, and ¹⁰Be obtained by (a) the AMD+VAP (variation after the angular-momentum and parity projections), (b) the variation after the parity projection without the angular-momentum projection, and (c) the variation without the angular-momentum and parity projections. The density integrated over the *x* axis is shown on the *z*-*y* plane in the $|z| \le 5$ fm and $|y| \le 5$ fm region.

As given in Eq. (1), an AMD wave function is expressed by a single Slater determinant. However, the projected state $P_{MK}^{J\pi} \Phi_{AMD}(\mathbf{Z}^0)$ for the ground state wave function contains higher correlations beyond mean-field approximations, which is efficiently described by the VAP calculation. Indeed, cluster structures are remarkable in the present VAP result but they are relatively suppressed in calculations without the projections. For comparison with the present result obtained by the VAP (variation after the angular-momentum and parity projections), the result obtained by the variation without the angularmomentum and parity projections and that after the parity projection without the angular-momentum projection are also demonstrated in Figs. 1(b) and 1(c), respectively. It is clearly seen that the result of ¹⁰Be obtained by the variation without the projections shows weak clustering with a parity-symmetric intrinsic structure [see the right-hand panels of Figs. 1(b) and 1(c)]. This indicates that the angular-momentum and parity projections in the energy variation are essential to obtain the parity-asymmetric structure with the ${}^{6}\text{He} + \alpha$ correlation in ¹⁰Be.

The root mean square radii of point-proton distribution of ⁸Be, ⁹Be, ¹⁰Be, and ⁴He calculated by the AMD+VAP are 2.73, 2.69, 2.43, and 1.64 fm, which are slightly larger than the experimental values, 2.39, 2.22, and 1.45 fm, of ⁹Be, ¹⁰Be, and ⁴He reduced from the charge radii. The calculated magnetic and electric quadrupole moments of ⁹Be are $\mu = -1.06\mu_N$ and $Q = 6.9 \ e \ fm^2$, which reasonably

FIG. 2. Schematic figures for the sets of unit vectors (a) $e_{\sigma=x,y,z}$, (b) $e_{\sigma=1,...,8}$, and (c) $e_{\sigma=1,...,14}$ used in the sAMD calculation.

agree to the experimental values, $\mu = -1.1778(9)\mu_N$ and $Q = 5.288(38) e \text{ fm}^2$.

C. Excited states

To investigate dipole excitations, I calculated the $J^{\pi} = 1^{-}$ states of ⁸Be, ¹⁰Be, and ⁴He, and $J^{\pi} = 1/2^+$, $3/2^+$, and $5/2^+$ states of ⁹Be by applying the sAMD based on the obtained ground state wave functions. The sAMD + α GCM is also applied to ⁹Be and ¹⁰Be. For the sAMD, the shift parameter ϵ is taken to be $\epsilon = 0.1$ fm, which is small enough to give the ϵ -independent result. For unit vectors \boldsymbol{e}_{σ} , I chose three sets, $e_{\sigma=x,y,z}$, $e_{\sigma=1,\dots,8}$, and $e_{\sigma=1,\dots,14}$, as shown in Fig. 2, and checked the convergence of the dipole strengths. Here, the set of 8 vectors is $e_{\sigma=1,...,8} = (\pm 1/\sqrt{3}, \pm 1/\sqrt{3}, \pm 1/\sqrt{3}),$ oriented to 8 corners of a cube, and that of 14 vectors is $e_{\sigma=1,...,14} = \{e_{\sigma=1,...,8}, e_x, e_y, e_z, -e_x, -e_y, -e_z\}.$ The x, y, and z axes are taken to be the principle axes of the inertia of the intrinsic state that satisfy $\langle x^2 \rangle \leq \langle y^2 \rangle \leq \langle z^2 \rangle$ and $\langle xy \rangle =$ $\langle yz \rangle = \langle zx \rangle = 0$. The *E*1 and ISD strengths of ⁹Be and ¹⁰Be calculated by the sAMD in three cases, $e_{\sigma=x,y,z}$, $e_{\sigma=1,...,8}$, and $e_{\sigma=1,\dots,14}$, are shown in Fig. 3. As expected, the set $e_{\sigma=x,y,z}$ gives the approximately converged result for the E1 strength but not for the ISD strength. It is found that the set $e_{\sigma=1,...,8}$ is practically enough to get a qualitatively converged result for both the E1 and ISD strengths, and therefore this set is adopted in the present calculation of the dipole strengths. For the α GCM calculation, the distance parameter is taken to be $\Delta D = -1, 1, 2, \dots, 20$ fm. In the ground state wave functions $\Phi_{\rm AMD}(\mathbf{Z}^0)$ of ⁹Be (¹⁰Be), the intercluster distance is $D_{\alpha} \sim 4$ fm (3 fm). Therefore, the choice of $\Delta D \leq 20$ fm means that α -cluster continuum states are treated as discretized states in the box boundary $D_{\alpha} \lesssim 24$ fm (23 fm).

The model space of the sAMD + α GCM wave function given in Eq. (17) covers 1p-1h excitations and α -cluster

FIG. 3. *E*1 and ISD strengths of ⁹Be and ¹⁰Be obtained by the sAMD in the three cases $e_{\sigma=x,y,z}$, $e_{\sigma=1,...,8}$, and $e_{\sigma=1,...,14}$. The smearing width is $\gamma = 2$ MeV.

excitations from the ground state wave function. For a detailed description of the low-lying energy spectra and their dipole transition strengths, I mixed additional configurations optimized for the low-lying levels ${}^{9}\text{Be}(1/2_{1}^{+})$, ${}^{9}\text{Be}(3/2_{1}^{+})$, ${}^{9}\text{Be}(5/2_{1}^{+})$, and ${}^{10}\text{Be}(1_{1}^{-})$, which are obtained by the AMD+VAP with $J^{\pi} = 1/2^{+}$, $3/2^{+}$, and $5/2^{+}$ for ${}^{9}\text{Be}$ and that with $J^{\pi} = 1^{-}$ for ${}^{10}\text{Be}$. The final wave function with these additional VAP configurations (cfg) is given as

$$\Psi_{\text{Be}(J_k^{\pi})}^{\text{sAMD}+lpha \text{GCM+cfg}}$$

$$= \sum_{K} c_0 (J_k^{\pi}; K) P_{MK}^{J\pi} \Phi_{AMD}(\mathbf{Z}^0)$$

$$+ \sum_{i=1,...,A} \sum_{\sigma} \sum_{K} c_1 (J_k^{\pi}; i, \sigma, K) P_{MK}^{J\pi} \Phi_{AMD} (\mathbf{Z}_{nonflip}^0(i, \sigma))$$

$$+ \sum_{i=1,...,A} \sum_{\sigma} \sum_{K} c_2 (J_k^{\pi}; i, \sigma, K) P_{MK}^{J\pi} \Phi_{AMD} (\mathbf{Z}_{flip}^0(i, \sigma))$$

$$+ \sum_{\Delta D} \sum_{K} c_3 (J_k^{\pi}; \Delta D, K) P_{MK}^{J\pi} \Phi_{AMD} (\mathbf{Z}_{D_{\alpha}}^0(\Delta D))$$

$$+ \sum_{J'\pi'} \sum_{K} c_4 (J_k^{\pi}; J'\pi', K) P_{MK}^{J\pi} \Phi_{AMD} (\mathbf{Z}_{VAP}^{J'\pi'}). \quad (28)$$

The dipole strengths are calculated by the following matrix elements:

$$\left\langle \Psi_{\mathrm{Be}(J_{\iota}^{\mathrm{SAMD}})}^{\mathrm{SAMD}} \middle| \left| \mathcal{M} \right| \middle| \Psi_{\mathrm{Be}(\mathrm{g.s.})}^{\mathrm{SAMD}} \right\rangle,\tag{29}$$

$$\left\langle \Psi_{\text{Be}(J_{k}^{\pi})}^{\text{sAMD}+\alpha\text{GCM}}\right|\left|\mathcal{M}\right|\left|\Psi_{\text{Be}(g.s.)}^{\text{sAMD}+\alpha\text{GCM}}\right\rangle,\tag{30}$$

$$\langle \Psi_{\text{Be}(J_{k}^{\pi})}^{\text{sAMD}+\alpha\text{GCM+cfg}} \big| \big| \mathcal{M} \big| \big| \Psi_{\text{Be}(g.s.)}^{\text{sAMD}+\alpha\text{GCM+cfg}} \rangle.$$
(31)

The calculated dipole strengths with and without the additional VAP configurations are found to be almost consistent with each other except for quantitative details of the energy position and the strengths in $E \leq 10$ MeV. In this paper, I mainly discuss the dipole strengths calculated by the sAMD and the sAMD + α GCM + cfg wave functions, which I call cal-I and cal-II, respectively. The former corresponds to the small

FIG. 4. Energy-weighted *E*1 strength of ⁹Be and ¹⁰Be obtained by the sAMD (cal-I) and the sAMD + α GCM + cfg (cal-II). The smearing width is $\gamma = 2$ MeV.

amplitude calculation containing 1p-1h excitations. The latter contains the large amplitude α -cluster mode in addition to the 1p-1h excitations described by the sAMD model space. Namely, the sAMD + α GCM + cfg includes the higher correlation than the sAMD in both the ground and excited states.

D. E1 strength

The energy-weighted E1 strength of ⁹Be and ¹⁰Be obtained by the sAMD (cal-I) and the sAMD + α GCM + cfg (cal-II) is shown in Fig. 4. The strength functions of two calculations (I) and (II) are qualitatively similar to each other except for broadening of the low-energy strength in $E \leq 15$ MeV of ⁹Be in cal-II. Figure 5 shows the comparison of the calculated E1 cross section with the experimental photonuclear cross sections of ⁹Be. In Table I, the EWS of the E1 strength in the low-energy (E < 20 MeV) and the GDR (20 < E < 50 MeV) regions and the total EWS in ⁹Be and ¹⁰Be obtained by the sAMD + α GCM + cfg (cal-II) are shown compared with the experimental values estimated by the experimental photonuclear cross sections [81,85]. The GDR energy calculated by the averaged energy in the 20 <E < 50 MeV region, $E_{\text{GDR}} = \int_{\text{GDR}} E dB(E1) / \int_{\text{GDR}} dB(E1)$, is also shown. The calculated total EWS of the E1 strength is enhanced from S(TRK) by a factor of 1.7. Compared with the experimental data for ⁹Be, the calculation overestimates the EWS in the low-energy and GDR regions by a factor of 1.6 and underestimates the width of the GDR, whereas it reasonably describes the GDR energy and also the ratio of the EWS in the low-energy region to that of the GDR.

FIG. 5. Comparison of the calculated *E*1 cross section of ⁹Be with the experimental photonuclear cross sections. The calculated values are those obtained with the sAMD + α GCM + cfg (cal-II), smeared by $\gamma = 2$ MeV. The experimental data are taken from the photonuclear cross sections by Ahrens *et al.* [85], the bremsstrahlung data by Goryachev *et al.* [81], and the photodisintegration cross sections by Utsunomiya *et al.* [84].

As shown in the comparison of the sAMD (cal-I) and the sAMD + α GCM + cfg (cal-II) in Fig. 4, the *E*1 strength of ⁹Be and ¹⁰Be is not affected so much by the coupling with the large amplitude α -cluster motion. In the following, I give a detailed analysis of the *E*1 strength of ⁸Be, ⁹Be, and ¹⁰Be based on the sAMD to discuss the effects of excess neutrons on the *E*1 strength in ⁹Be and ¹⁰Be.

Figure 6 shows the *E*1 strength of ⁸Be, ⁹Be, ¹⁰Be, and ⁴He calculated by the sAMD. For ⁹Be, decomposition of the transition strength to $J = 1/2^+$, $3/2^+$, and $5/2^+$ states is also shown. The GDR in ⁸Be shows a two-peak structure in E = 20-40 MeV in contrast to the single-peak structure of the GDR in ⁴He. Also in ⁹Be, the two-peak structure of the GDR is seen but it somewhat broadens. In addition to the GDR, low-lying *E*1 strength appears in E = 10-20 MeV of ⁹Be. In ¹⁰Be, the lower peak of the GDR exists at $E \sim 25$ MeV, whereas the higher peak of the GDR is largely fragmented. Below the GDR, an *E*1 resonance appears at $E \sim 15$ MeV.

The origin of the two-peak structure of the GDR in Be isotopes is the prolate deformation of the 2α core. To

TABLE I. EWS of the *E*1 strength in the low-energy (E < 20 MeV) and the GDR (20 < E < 50 MeV) regions and the total EWS of ⁹Be and ¹⁰Be. The values in parentheses are the ratios to the TRK sum rule [S(TRK) = 33.0 fm² MeV for ⁹Be and S(TRK) = 35.6 fm² MeV for ¹⁰Be]. The calculated values are those obtained by the sAMD + α GCM + cfg (cal-II). The GDR energy is also shown. For ⁹Be, the data evaluated from the experimental photonuclear cross sections [81,85] are listed. The unit of S(E1) is fm² MeV.

FIG. 6. Energy-weighted E1 strength of ⁸Be, ⁹Be, and ¹⁰Be obtained by the sAMD ($\sigma = 1, ..., 8$) and the sAMD-z (longitudinal mode, $\sigma = z$) calculations. The sAMD and sAMD-z results for (a) ⁸Be, (b) ⁹Be, and (d) ¹⁰Be are shown by solid and dashed lines, respectively. The decomposition of the strengths for $J^{\pi} = 1/2^+$, $3/2^+$, and $5/2^+$ states of ⁹Be is also shown as well as the total strength in (c). For comparison, the energy-weighted E1 strength of ⁴He obtained by the sAMD ($\sigma = 1, ..., 8$) is also shown in (a). The smearing width is $\gamma = 2$ MeV.

distinguish the longitudinal mode in the intrinsic frame, we calculate the E1 strength in the truncated sAMD model space by using wave functions shifted only to the longitudinal (z)

direction, that is, the sAMD with fixed $\sigma = z$ as

$$\Psi_{\text{Be}(J_{k}^{\pi})}^{\text{sAMD-z}} = c_{0}(J_{k}^{\pi})P_{MK}^{J\pi}\Phi_{\text{AMD}}(\mathbf{Z}^{0}) + \sum_{i=1,...,A} \left\{ c_{1}(J_{k}^{\pi};i)P_{M0}^{J\pi}\Phi_{\text{AMD}}(\mathbf{Z}_{\text{nonflip}}^{0}(i,z)) + c_{2}(J_{k}^{\pi};i)P_{M0}^{J\pi}\Phi_{\text{AMD}}(\mathbf{Z}_{\text{flip}}^{0}(i,z)) \right\},$$
(32)

where the coefficients c_0 , c_1 , and c_2 are determined by diagonalization of the norm and Hamiltonian matrices. Here I omit the *K*-mixing and fix K = 0 for ⁸Be and ¹⁰Be, and K = 3/2 for ⁹Be to take into account only the Y_0^1 mode in the intrinsic frame. The sAMD with $\sigma = z$, which I call "sAMDz," is approximately regarded as the calculation containing the longitudinal mode but no transverse mode, though two modes do not exactly decouple from each other because of the angular-momentum projection. The *E*1 strength obtained by the sAMD-z is shown by dashed lines in Figs. 6(a), 6(b), and 6(d). In comparison of the sAMD and sAMD-z results, it is found that the lower peak of the GDR at E = 20-30 MeV is contributed by the longitudinal mode of the 2α core, whereas the higher peak of the GDR comes from the transverse mode. The higher peak broadens in ⁹Be and it is largely fragmented in

¹⁰Be, indicating that the transverse mode is affected by excess neutrons. For the low-lying *E*1 resonances below the GDR, the strength at $E \sim 10$ MeV in ⁹Be and that at $E \sim 15$ MeV in ¹⁰Be are mainly contributed by the longitudinal mode. These low-energy dipole resonances in ⁹Be and ¹⁰Be are understood by the longitudinal motion of valence neutrons against the 2α core.

From the above analysis of the E1 strength of ⁹Be and ¹⁰Be compared with that of ⁸Be, the effects of excess neutrons on the E1 strength is understood as follows. The longitudinal and transverse dipole modes in the 2α core part contribute to the GDR with the two-peak structure. The valence neutron modes couple with the transverse dipole mode of the 2α core and they broaden the higher peak of the GDR. Moreover, the valence neutron modes against the 2α core contribute to the low-energy E1 strength. More details of the low-energy dipole excitations are discussed later.

E. ISD strength and coupling with the α -cluster mode in ⁹Be and ¹⁰Be

As previously mentioned, the sAMD (cal-I) corresponds to the small amplitude calculation, whereas the sAMD + α GCM + cfg (cal-II) contains the large amplitude α -cluster mode. A possible enhancement of the ISD strength in cal-II relative to cal-I can be a good probe for the dipole excitation that couples with the α -cluster mode, because the α -cluster excitation in ⁹Be and ¹⁰Be involves the compressive dipole mode. The energy-weighted ISD strength of ⁹Be and ¹⁰Be calculated by cal-I and cal-II is shown in Fig. 7. The strength of the isoscalar GDR in $E = 30 \sim 50$ MeV is not affected by the α -cluster mode, whereas the ISD strength for some low-energy resonances are significantly enhanced in cal-II as a result of the coupling with the α -cluster mode. In ⁹Be, the ISD strength in E < 10 MeV is remarkably enhanced in cal-II, whereas the resonance at E = 10-15 MeV has the

FIG. 7. ISD strength of ⁹Be and ¹⁰Be obtained by the sAMD (cal-I) and the sAMD + α GCM + cfg (cal-II). *E*1 strength obtained by the the sAMD + α GCM + cfg (cal-II) is also shown for comparison. The smearing width is $\gamma = 2$ MeV.

weak ISD strength in both cal-I and cal-II. In ¹⁰Be, the ISD strength around E = 15 MeV is enhanced.

F. Low-energy dipole resonances in ⁹Be and ¹⁰Be

From the analysis of the *E*1 and ISD strengths, the low-energy dipole excitations below the GDR in ⁹Be can be categorized as three resonances in *E* < 8 MeV, 8 < *E* < 15 MeV, and 15 < *E* < 20 MeV, which I label A1, A2, and A3 resonances, respectively. The A1 resonance contains the contribution from the low-lying positive-parity states, ⁹Be(1/2₁⁺), ⁹Be(3/2₁⁺), and ⁹Be(5/2₁⁺), which are discussed in detail later. The EWS in the corresponding energy regions, *S*(*E*1/IS1; A1), *S*(*E*1/IS1; A2), and *S*(*E*1/IS1; A3), is listed in Table II as well as the total EWS value. In addition to the EWS obtained by the sAMD (cal-I) and sAMD + α GCM + cfg (cal-II), the EWS calculated by the matrix elements

$$\left\langle \Psi_{\text{Be}(J_{k}^{\pi})}^{\text{sAMD}} \middle| \mathcal{M} \middle| \Psi_{\text{Be}(g.s.)}^{\text{sAMD} + \alpha \text{GCM+cfg}} \right\rangle$$
(33)

for the transitions from the sAMD + α GCM + cfg initial states to the sAMD final states (cal-III) and that by the matrix elements

$$\left\langle \Psi_{\text{Be}(J_{k}^{\pi})}^{\text{sAMD}+\alpha\text{GCM+cfg}} \left| \mathcal{M} \right| \Psi_{\text{Be}(g.s.)}^{\text{sAMD}} \right\rangle \tag{34}$$

for the transitions from the sAMD initial states to the sAMD + α GCM + cfg final states (cal-IV) are also shown

TABLE II. EWS of the *E*1 and ISD strengths for low-energy resonances: A1 (E < 8 MeV), A2 (8 < E < 15 MeV), and A3 (15 < E < 20 MeV) in ⁹Be, and B1 (E < 12 MeV) and B2 (12 < E < 20 MeV) in ¹⁰Be. The total EWS is also shown. The strengths are calculated by the sAMD (cal-I) and the sAMD + α GCM + cfg (cal-II). The EWS calculated by the matrix elements for the transitions from the sAMD + α GCM + cfg initial states to the sAMD final states (cal-III), and that for the transitions from the sAMD + α GCM + cfg final states (cal-IV) are also listed. The unit of *S*(*E*1) is fm² MeV and that of *S*(ISD) is fm⁶ MeV.

<i>S</i> (IS1; B2)	56	187	83	74					

in the table. Here cal-III contains the α -cluster mode in the initial states as the ground state correlation but not in the final states, whereas cal-IV contains the α -cluster mode only in the final states but not in the initial states. In all the calculations (cal-I, cal-II, cal-III, and cal-IV), S(E1; A1) is very small, whereas S(E1; A2) and S(E1; A3) are significantly large as $\sim 10\%$ of the TRK sum rule. Consequently, the EWS of the E1 strength in E < 20 MeV exhausts $\sim 20\%$ of the TRK sum rule and it is $\sim 10\%$ of the calculated total EWS.

The α -cluster mode does not affect so much the *E*1 and ISD strengths of A2 and those of A3, but it gives significant enhancement of the dipole strengths of A1. In particular, S(IS1; A1) is remarkably enhanced by the coupling with the α -cluster mode. The enhancement is found only in cal-II but not in other calculations (cal-I, cal-III, and cal-IV). It indicates that the coupling with the α -cluster mode in the ground state and that in the A1 resonance coherently enhance S(IS1; A1). The α -cluster mode also makes S(E1; A1) three times larger in cal-II than in cal-I, though it is still less than 2% of the TRK sum rule.

As seen in the EWS of the sAMD + α GCM + cfg (cal-II) in Table II, the A1 resonance shows relatively strong ISD and weak *E*1 transitions, whereas the A2 resonance shows relatively weak ISD and strong *E*1 transitions. In the sAMD + α GCM + cfg, the wave functions for these resonances are expressed by the linear combination of many configurations; however, each of the low-lying resonances has

FIG. 8. Schematic figures of 2α and valence neutrons for the ground state and the A1 and A2 resonances of ⁹Be, and those for the ground state and the B1 and B2 resonances of ¹⁰Be.

a dominant component given by the single J^{π} -projected AMD wave function obtained by the AMD + VAP. Based on the analysis of the single-particle wave functions in the dominant component, the above-mentioned characteristics of the A1 and A2 resonances can be understood by the molecular orbital $2\alpha + n$ picture as follows.

The ground and low-lying states of ⁹Be are approximately described by the molecular orbital structure, where the valence neutron occupies molecular orbitals formed by the linear combination of *p* orbits around α clusters as already discussed in Refs. [86,87,114,115]. Let me consider two α clusters at the left and right along the *z* axis (see Fig. 8). I call the left (right) α " $\alpha_{L(R)}$," and label single-particle orbits (atomic orbitals) around each α cluster as $[Nn_z l_z j_z]_{\alpha_{L(R)}}$. Here *N* is the total quantum (node) number, n_z is the quantum number for the *z* axis, and l_z and j_z are the *z* components of the orbital and total-angular momenta, respectively. The $\pi_{3/2}^-$ and $\pi_{3/2}^+$ molecular orbitals are given by the linear combination of the atomic orbitals $[101\frac{3}{2}]_{\alpha_{L,R}}$ as

$$\pi_{3/2}^{-} \equiv \left[101\frac{3}{2}\right]_{\text{MO}} = \left[101\frac{3}{2}\right]_{\alpha_L} + \left[101\frac{3}{2}\right]_{\alpha_R}, \quad (35)$$

$$\pi_{3/2}^{+} \equiv \left[211\frac{3}{2}\right]_{\rm MO} = \left[101\frac{3}{2}\right]_{\alpha_L} - \left[101\frac{3}{2}\right]_{\alpha_R}, \quad (36)$$

where $[Nn_z l_z j_z]_{MO}$ is the label indicating the quantum numbers N, n_z , l_z , and j_z of the molecular orbital around the 2α . Another molecular orbital is the longitudinal orbital $\sigma^+_{1/2}$ given by the linear combination of $[110\frac{1}{2}]_{\alpha_{L,R}}$ as

$$\sigma_{1/2}^{+} \equiv \left[220\frac{3}{2}\right]_{\rm MO} = \left[110\frac{1}{2}\right]_{\alpha_L} - \left[110\frac{1}{2}\right]_{\alpha_R}.$$
 (37)

In the case that the α - α distance is not so large, the molecular orbital $[Nn_z l_z j_z]_{MO}$ approximately corresponds to the Nilsson (deformed shell-model) orbit $[Nn_3\Lambda]_{\Omega}$ with $n_3 = n_z$, $\Lambda = l_z$, and $\Omega = j_z$ in the prolate deformation. $\pi_{3/2}^-$ is the negative-parity orbital with no node $(n_z = 0)$, $\pi_{3/2}^+$ is the positive-parity orbital with one node $(n_z = 1)$, and $\sigma_{1/2}^+$ is the positive-parity orbital with two nodes $(n_z = 2)$ along the *z* axis. For the valence neutron around the 2α , $\pi_{3/2}^-$ is the lowest negative-parity orbital, whereas $\sigma_{1/2}^+$ is the lowest positive-parity orbital.

The ground state of ⁹Be dominantly has the $2\alpha + n$ structure with the $\pi_{3/2}^-$ configuration. The A1 resonance is approximately described by the $\sigma_{1/2}^+$ configuration, whereas the A2 resonance is dominated by the $\pi^+_{3/2}$ configuration (see Fig. 8). The E1 transition for $\pi_{3/2}^- \rightarrow \pi_{3/2}^+$, i.e., $[101\frac{3}{2}]_{MO} \rightarrow$ $[211\frac{3}{2}]_{MO}$, is possible because the Y_0^1 operator changes $N \rightarrow N \pm 1$ and $n_z \rightarrow n_z \pm 1$. However, the E1 transition for $\pi_{3/2}^- \to \sigma_{1/2}^+$, i.e., $[101\frac{3}{2}]_{MO} \to [220\frac{1}{2}]_{MO}$, is forbidden because the change $n_z \rightarrow n_z \pm 2$ is not possible for the E1 operator. This is the reason why the E1 strength is large for A2 but it is suppressed for A1. Because of the $[211\frac{3}{2}]_{MO}$ configuration of the A2 resonance, the E1 strength of A2 shows the K = 3/2 band feature that the contribution from transitions to $J^{\pi} = 3/2^+$ and $5/2^+$ states is dominant as seen in Fig. 6(c). The A1 resonance has the larger node number $n_z = 2$ along the 2α direction than the A2 resonance ($n_z = 1$) and, therefore, the spatial development of the 2α clustering is more prominent in the A1 resonance. As a result of the developed clustering, the A1 resonance couples rather strongly with the α -cluster mode. The coupling with the α -cluster mode, namely, the ⁵He - α relative motion in A1, enhances the ISD strength as discussed previously.

In Fig. 9, I show the single-particle wave function of the valence neutron around the 2α core in the dominant components of the ground state, A1, and A2 resonances. The analysis of the single-particle wave functions is similar to that done in Ref. [106] for ¹⁰Be. The dominant components of the ground state and the A1 resonance of ⁹Be are $P_{MK}^{J\pi} \Phi_{\text{AMD}}(\mathbf{Z}_{\text{VAP}}^{J\pi})$ obtained by the VAP for $J^{\pi} = 3/2^{-}$ and $J^{\pi} = \{1/2^+, 3/2^+, 5/2^+\}$, respectively. The A2 resonance is dominated by the $3/2^+$ and $5/2^+$ components projected from $\Phi_{AMD}(\mathbf{Z}_{VAP}^{3/2-} = \mathbf{Z}^0)$ obtained by the VAP for the ground state. It is found that the negative-parity and positive-parity components of the valence neutron in $\Phi_{AMD}(\mathbf{Z}^0)$ approximately correspond to the molecular $\pi_{3/2}^-$ and $\pi_{3/2}^+$ orbitals [see Figs. 8(a) and 8(c)], respectively, and the positive-parity component of the valence neutron in $\Phi_{AMD}(\mathbf{Z}_{VAP}^{J\pi})$ for $J^{\pi} = 1/2^+$, $J^{\pi} = 3/2^+$, and $J^{\pi} = 5/2^+$ shows the two-node structure corresponding approximately to the molecular $\sigma_{1/2}^+$ orbital [see Fig. 8(b)]. These results support the above-mentioned interpretation of the ground state, A1, and A2 resonances with the molecular $\pi_{3/2}^-$, $\sigma_{1/2}^+$, and $\pi_{3/2}^+$ orbitals, respectively.

Let me discuss low-energy dipole resonances in ¹⁰Be. The low-energy dipole strength below the GDR can be categorized as two resonances in E < 12 MeV and 12 < E < 20 MeV, which I label B1 and B2, respectively. The EWS of the dipole strengths for the corresponding energy regions are

FIG. 9. Valence neutron wave functions in the intrinsic wave functions, $\Phi_{AMD}(Z_{VAP}^{J\pi})$, of ⁹Be obtained by the VAP for $J^{\pi} = 3/2^{-}$ and $J^{\pi} = \{1/2^{+}, 3/2^{+}, 5/2^{+}\}$. The distribution of the total density is shown on the left. The density distributions of the positive- and negative-parity components of the valence neutron wave function are shown in the middle and on the right. The total density is normalized to be the nucleon number *A*, whereas each of the positive- and negative-parity components is normalized to be 1 and the factor 8 is multiplied in the illustration. The percentages of the positive and negative components are also shown. The density integrated over the *x* axis is shown on the *z*-*y* plane in the $|z| \leq 5$ fm and $|y| \leq 5$ fm region.

listed in Table II. The B2 resonance shows the strong *E*1 transition exhausting more than 20% of the TRK sum rule and 10% of the calculated total EWS. It also shows the significant ISD strength enhanced by the α -cluster mode in cal-II (sAMD + α GCM + cfg). The significant *E*1 strength and the strong coupling with the α -cluster mode of the B2 resonance can be understood by two-neutron correlation in the $2\alpha + 2n$ picture as shown in the schematic figures of Fig. 8. The configuration in the ground state of ¹⁰Be is approximately described by the positive-parity projected state of the atomic orbital configuration as

$$\begin{bmatrix} 101\frac{3}{2} \end{bmatrix}_{\alpha_L} \begin{bmatrix} 10 - 1 - \frac{3}{2} \end{bmatrix}_{\alpha_L} + \begin{bmatrix} 101\frac{3}{2} \end{bmatrix}_{\alpha_R} \begin{bmatrix} 10 - 1 - \frac{3}{2} \end{bmatrix}_{\alpha_R} \\ = \frac{1}{2} \{ (\pi_{3/2}^{-})^2 + (\pi_{3/2}^{+})^2) \},$$
(38)

FIG. 10. *E*1 strength of $1/2^+$, $3/2^+$, and $5/2^+$ states of ⁹Be in *E* < 10 MeV obtained by (a) sAMD (cal-I) and (b) sAMD + α GCM + cfg (cal-II). The smearing width is $\gamma = 0.1$ MeV.

which corresponds to the ⁶He + α cluster structure in the intrinsic state of the ¹⁰Be ground state. The B2 resonance has 50% overlap with the negative-parity state $P_{00}^{1-}\Phi_{AMD}(\mathbf{Z}^0)$ projected from the intrinsic wave function for the ground state and, hence, the B2 resonance is interpreted as the parity partner of the ground state as

$$\begin{bmatrix} 101\frac{3}{2} \end{bmatrix}_{\alpha_L} \begin{bmatrix} 10 - 1 - \frac{3}{2} \end{bmatrix}_{\alpha_L} - \begin{bmatrix} 101\frac{3}{2} \end{bmatrix}_{\alpha_R} \begin{bmatrix} 10 - 1 - \frac{3}{2} \end{bmatrix}_{\alpha_R} = \frac{1}{2} \{ \pi_{3/2}^- \pi_{3/2}^+ + \pi_{3/2}^+ \pi_{3/2}^- \}.$$
(39)

In the transition from the ground state to the B2 resonance, the coherent contribution of two neutrons enhances the E1strength. The B2 resonance has also a large overlap with negative-parity ⁶He $+ \alpha$ cluster wave functions, for instance, 60% overlap with $P_{00}^{1-}\Phi_{AMD}(\mathbf{Z}_{D_{\alpha}}^{0}(\Delta D=1 \text{ fm}))$. As a result of the strong coupling with the α -cluster mode, the ISD strength of the B2 resonance is enhanced. In other words, the B2 resonance is regarded as the α -cluster excitation on the ground state which already contains the ${}^{6}\text{He} + \alpha$ cluster structure. In contrast to the B2 resonance, the B1 resonance is regarded as a single-particle excitation with the molecular orbital configuration $\pi_{3/2}^- \sigma_{1/2}^+$ from the analysis of the single-particle wave functions as discussed for ${}^{10}Be(1_1^-)$ in Ref. [106]. This configuration has no coherent contribution of two neutrons to the E1 strength. Moreover, the $\pi_{3/2}^- \sigma_{1/2}^+$ configuration contains the ⁵He + ⁵He and ⁶He^{*} + α components instead of the ⁶He + α component and, therefore, it does not couple with the α -cluster mode.

Finally, I discuss the calculated B(E1) of the $1/2_1^+$, $3/2_1^+$, and $5/2_1^+$ states of ⁹Be, which contribute to the dipole strengths of the A1 resonance. In Fig. 10, I show the *E*1 strength in $E \le 10$ MeV of ⁹Be. Here the smearing width is chosen to be $\gamma = 0.1$ MeV to resolve discrete states. The $1/2_1^+$, $3/2_1^+$,

TABLE III. Excitation energy and *E*1 strength of ${}^{9}\text{Be}(1/2_{1}^{+})$, ${}^{9}\text{Be}(3/2_{1}^{+})$, ${}^{9}\text{Be}(5/2_{1}^{+})$, and ${}^{10}\text{Be}(1_{1}^{-})$. The energy (MeV) and *B*(*E*1) (fm²) calculated by the sAMD (cal-I) and the sAMD + α GCM + cgf (cal-II) are listed compared with the experimental data. The experimental values of ${}^{9}\text{Be}$ are data measured by the (γ , *n*) cross sections in Ref. [83]. The experimental excitation energy of ${}^{10}\text{Be}(1^{-})$ is taken from Refs. [116,117].

	cal-I		cal-II		Expt.	
	E	B(E1)	E	B(E1)	E	<i>B</i> (<i>E</i> 1)

and $5/2_1^+$ states are obtained as discrete states in the sAMD (cal-I). In the sAMD + αGCM + cfg (cal-II), the $1/2^+_1$ and $5/2_1^+$ states are still discrete states; however, the $3/2_1^+$ state shows a resonance behavior coupling with the discretized continuum states in the box boundary at $D_{\alpha} \lesssim 24$ fm. We evaluate B(E1) of the $3/2^+_1$ resonance by a sum of the E1 strength in E < 6 MeV and estimate the excitation energy by the B(E1) weighted-averaged energy of $3/2^+$ states in this energy region. In Table III, I compare the calculated E1 strength of the $1/2_1^+$, $3/2_1^+$, and $5/2_1^+$ states with the experimental values measured by the (γ, n) cross sections in Ref. [83]. The excitation energies and B(E1) of ${}^{9}\text{Be}(5/2_{1}^{+})$ and ${}^{9}\text{Be}(3/2_{1}^{+})$ obtained by the sAMD + α GCM + cfg (cal-II) reproduce reasonably the experimental data, whereas the calculated B(E1) of ${}^{9}\text{Be}(1/2_1^+)$ is quite small, inconsistently with the experimental data. The $1/2_1^+$ state has been suggested to be a virtual or resonance state of an s-wave neutron [91–97]. However, the present model is insufficient to describe such a virtual or s-wave resonance state because of the valence neutron motion far from the 2α . It means that neutron decay is not taken into account in the model space even though the calculated one-neutron separation energy ($S_n = 0.5 \text{ MeV}$ in the AMD + VAP and $S_n = 2.1$ MeV in the sAMD) is not so much different from the experimental value ($S_n =$ 1.67 MeV). In the present calculation, ${}^{9}Be(1/2^{+}_{1}), {}^{9}Be(3/2^{+}_{1}),$ and ${}^{9}\text{Be}(5/2^+_1)$ dominantly have the $2\alpha + n$ structure with a valence neutron in the $\sigma_{1/2}^+$ orbital as described previously. Since the intrinsic structures of the dominant components of these three states are similar to each other as shown in Fig. 9, they are approximately regarded as the band members of the $K^{\pi} = 1/2^+$ rotational band. It should be commented that only ${}^{9}\text{Be}(3/2_{1}^{+})$ and ${}^{9}\text{Be}(5/2_{1}^{+})$ contribute to the ISD strength of the A1 resonance because of the coupling with the cluster mode, but ${}^{9}\text{Be}(1/2_{1}^{+})$ gives almost no contribution to the dipole strengths in the present result.

V. SUMMARY

I investigated the isovector and isoscalar dipole excitations in ⁹Be and ¹⁰Be with the shifted basis AMD combined with the α -cluster GCM, in which the 1p-1h excitation modes built on the ground state and the large amplitude α -cluster mode are taken into account. Since the angular-momentum and parity projections are done, the coupling of excitations in the intrinsic frame with the rotation and parity transformation is taken into account microscopically. The low-energy *E*1 resonances appear in E < 20 MeV because of valence neutron modes against the 2α core. They exhaust about 20% of the TRK sum rule and 10% of the calculated EWS. The GDR shows the two-peak structure which is understood by the *E*1 excitations in the 2α core part with the prolate deformation. The higher peak of the GDR for the transverse mode broadens in ⁹Be and it is largely fragmented in ¹⁰Be because of excess neutrons.

By comparing the results of the shifted basis AMD combined with and without the α -cluster GCM, I investigated how the *E*1 and ISD strengths in ⁹Be and ¹⁰Be are affected by the large amplitude α -cluster mode. The ISD strength is a good probe to identify the dipole resonances that couple with the α -cluster mode because the α -cluster mode in ⁹Be and ¹⁰Be involves the compressive dipole mode. It was found that the ISD strengths for some low-energy resonances in ⁹Be and ¹⁰Be are enhanced by the coupling with the α -cluster mode, whereas the *E*1 strength is not so sensitive to the coupling with the α -cluster mode. In ⁹Be, the ISD strength of the low-energy resonance in *E* < 10 MeV is remarkable. In ¹⁰Be, the ISD strength at $E \sim 15$ MeV is enhanced by the coupling with the α -cluster mode. This resonance at $E \sim 15$ MeV in ¹⁰Be is regarded as the α -cluster excitation on the ground state

having the ${}^{6}\text{He} + \alpha$ structure and can be interpreted as the parity partner of the ground state. The *E*1 transition of this resonance is also strong because of the coherent contribution of two valence neutrons.

Compared with the experimental E1 strength of ⁹Be estimated by the photonuclear cross sections, the calculation overestimates the EWS in the low-energy (E < 20 MeV) and GDR (20 < E < 50 MeV) regions by a factor of 1.6 and underestimates the width of the GDR, whereas it reasonably describes the GDR energy and also the ratio of the EWS in the low-energy region to that of the GDR. For the low-lying positive-parity states of ⁹Be, the calculated excitation energies and B(E1) of ⁹Be($5/2_1^+$) and ⁹Be($3/2_1^+$) reasonably agree with the experimental data. However, the calculation fails to reproduce the experimental B(E1) of ⁹Be($1/2_1^+$) because the present model is insufficient to describe the detailed asymptotic behavior of the *s*-wave neutron in the $1/2_1^+$ state.

ACKNOWLEDGMENTS

The author would like to thank Dr. Utsunomiya and Dr. Kikuchi for fruitful discussions. The computational calculations of this work were performed by using the supercomputer in the Yukawa Institute for theoretical physics, Kyoto University.
