Magnetic properties of mixed-valence iron phosphate glasses, where there coexist Fe^{2+} and Fe^{3+} ions, have been investigated. The molar fraction of Fe^{3+} with respect to the total iron ion, [Fe^{3+}]/[Fe_{total}], can be controlled by melting the glass at varied temperatures. Experiments of magnetic aging and memory effects as well as dynamic and static scaling analyses of relaxation time and nonlinear magnetic susceptibility have been performed to get insight into the nature of low-temperature magnetic phase of the glass system. The experimental results reveal that the iron phosphate glasses undergo paramagnet-spin-glass transitions at low temperatures. Temperature dependence of magnetic specific heat suggests that as the temperature is lowered, the magnetic moments start to be frozen at a temperature significantly higher than the spin-glass transition temperature accompanied by a deviation in magnetic susceptibility from Curie-Weiss law. The ratio of the absolute value of Weiss temperature to spin-glass transition temperature increases as the ratio [Fe^{3+}]/[Fe_{total}] becomes larger. This behavior is explainable in terms of the difference in single-ion anisotropy between Fe^{3+} and Fe^{2+} ions.

I. INTRODUCTION

A considerable attention has been paid to spin glass because of the expectation that it can be a physical model of random frustrated systems. The extensive search for new spin-glass materials and investigation of their magnetic properties have been performed since Cannella and Mydosh observed magnetic transitions in temperature dependence of susceptibility for binary AuFe alloys with very low concentrations of Fe. A great number of magnetic materials exhibiting the spin-glass behavior have emerged in crystalline alloys, oxides, sulfides, and so forth. Development of experimental, theoretical, and numerical studies on spin glasses has given an insight into their intrinsic nature. Even in this decade, fascinating phenomena involving magnetic aging effects have been reported as unique features of spin glasses.

Spin glass is also a matter of absorbing interest in this decade, fascinating phenomena involving magnetic glasses has given an insight into their intrinsic nature. Even experimental, theoretical, and numerical studies on spin glasses have been performed since Cannella and Mydosh observed magnetic transitions in temperature dependence of susceptibility for binary AuFe alloys with very low concentrations of Fe. A great number of magnetic materials exhibiting the spin-glass behavior have emerged in crystalline alloys, oxides, sulfides, and so forth. Development of experimental, theoretical, and numerical studies on spin glasses has given an insight into their intrinsic nature. Even in this decade, fascinating phenomena involving magnetic aging effects have been reported as unique features of spin glasses.

Magnetic oxide glass is a prototype of a solid in which magnetic moments are spatially distributed in a disordered fashion like spin glass. In most insulating oxide glasses, magnetic properties are dominated by antiferromagnetic superexchange interaction via an oxide ion. It may be naturally anticipated that all the pairs of magnetic moments antiferromagnetically coupled with each other cannot take their own most stable states because of the random distribution of magnetic ions. In other words, the magnetic frustration is inevitably present in the random structure of oxide glasses. Hence, magnetic oxide glass presumably satisfies the conditions necessary for the spin-glass transition: randomness and frustration. To clarify the mechanism of magnetic transition in oxide glasses, many studies have been performed on temperature dependence of dc and ac magnetic susceptibilities, Mössbauer spectrum, electron-spin-resonance spectrum, and so forth. As a result, magnetic oxide glasses, in particular, those containing 3d transition-metal ions, have been regarded as a prototype of insulating spin glass. Recently, we have reported that Fe_{2}O_{3}-TeO_{2} glasses manifest curious phenomena relevant to spin dynamics, including magnetic aging and memory effects as well as critical slowing down similar to those observed in canonical spin glasses. The result strongly confirms that Fe_{2}O_{3}-TeO_{2} glass system is a typical example of spin glass.

However, there have been few reports about the effect of sorts and chemical states of magnetic ions on the magnetic properties of amorphous insulating spin glasses. One transition-metal ion can take different valence states, leading to the difference in magnetic moment and single-ion anisotropy. For instance, high-spin Fe^{3+} has a 3d^{5} electronic configuration with S=5/2 and completely quenched orbital moment, while high-spin Fe^{2+} has a 3d^{6} electronic configuration with S=2 and possibly unquenched orbital moment. So, a drastic change in magnetic properties is expected when the valence state of magnetic ion is altered in oxide glasses. This paper focuses on iron phosphate glasses in which the valence state of Fe ion can be either divalent or trivalent. Wedgwood et al. performed neutron magnetic scattering for 0.79Fe_{2}O_{3}.P_{2}O_{5} glass and confirmed that the short-range antiferromagnetic ordering takes place at temperatures as low as 4.2 K. Shaw et al. observed spin-glass-like behavior in temperature dependence of dc magnetic susceptibility for xFe_{2}O_{3}.(100-x)P_{2}O_{5} glasses (30≤x≤44, in mol %). Recently we have reported that 57.1FeO.42.9P_{2}O_{5} glass exhibits spin-glass transition at 3.1 K as indicated by its temperature dependent magnetic susceptibility. However, detailed magnetic properties of iron phosphate glasses have not been investigated; especially, the dependence of magnetic behavior on the valence state of iron ions has not been discussed at all.

In this paper, the iron phosphate glasses with varied [Fe^{3+}]/[Fe_{total}] molar ratio have been prepared by melting in an alumina or a glassy carbon crucible at various temperatures, and their magnetic properties have been investigated in detail. These experimental procedures are described in Sec. II. In Sec. III, the valence state of Fe ion and the local structure of Fe ion are discussed in terms of ⁵⁷Fe Mössbauer
spectroscopy. In Sec. IV, we present the results of magnetic-susceptibility measurements and analyze the data on the basis of Curie-Weiss law and scaling law. Here, the spin-glass behavior of iron phosphate glasses is indicated by not only the magnetic aging and memory experiments but also the dynamic and static scaling analyses of relaxation time and nonlinear magnetic susceptibility. In Sec. V, we describe the results of magnetic specific-heat measurements. The results suggest that the short-range magnetic correlation emerges near the temperature at which magnetic susceptibility deviates from the Curie-Weiss law, and the correlation length gradually grows as the temperature is decreased. In Sec. VI, we describe the dependence of magnetic parameters including the spin-freezing temperature, \( T_f \), and Weiss temperature, \( \theta_W \), on the glass composition and oxidation state of iron ions in the glasses. Here, it is found that the value of \( \left| \theta_W \right| / T_f \) becomes lower with a decrease in \( [\mathrm{Fe}^{3+}] / [\mathrm{Fetotal}] \) ratio. The decrease in \( \left| \theta_W \right| / T_f \) is discussed in terms of the strong single-ion anisotropy of \( \mathrm{Fe}^{2+} \) ions. We also discuss the effects of the single-ion anisotropy on the dynamic and static aspects of magnetic properties of the present glasses. The conclusions are summarized in Sec. VII.

II. EXPERIMENTAL PROCEDURE

Glasses with nominal compositions of \( x\mathrm{Fe}_2\mathrm{O}_3 \cdot (100-x)\mathrm{P}_2\mathrm{O}_5 \) \((x=33, 37, 40, \text{ and } 45, \text{ in mol }\%\) were prepared from reagent grade \( \mathrm{Fe}_2\mathrm{O}_3 \) powder and \( \mathrm{H}_3\mathrm{PO}_4 \) aqueous solution by using a conventional melt-quenching method. After appropriate amounts of the starting materials were mixed thoroughly, the mixture was heated at 180 \(^\circ\)C to remove \( \mathrm{H}_2\mathrm{O} \) and then melted at \( T_m = X^\circ\)C \((X = 1200, 1350, \text{ and } 1500) \) for 30 min in an alumina crucible. The melt was poured onto a stainless-steel plate and cooled in air. The glass samples are denoted as \( x\mathrm{Fe}(100-x)\mathrm{PX} \) for convenience sake; for instance, \( 33\mathrm{Fe}67\mathrm{P1200} \) means that the mixture with a nominal composition of \( 33\mathrm{Fe}_2\mathrm{O}_3 \cdot 67\mathrm{P}_2\mathrm{O}_5 \) (mol \%) was melted at 1200 \(^\circ\)C. The as-quenched glass was pulverized, and then remelted in a glassy carbon crucible placed in an alumina crucible with an alumina lid at 1200 \(^\circ\)C for 30 min in air.\(^{13}\) The melt was cooled to room temperature. The glass samples melted in a glassy carbon crucible are denoted as \( x\mathrm{Fe}(100-x)\mathrm{PC} \) \((x=33, 37, \text{ and } 40, \text{ in mol }\%\). The amorphous nature of the samples was confirmed by x-ray diffraction analysis with Cu \( K\alpha \) radiation. \(^{57}\)Fe Mössbauer spectroscopy was carried out at room temperature employing \( ^{57}\)Co in metallic Rh as a \( \gamma \)-ray source so as to estimate valence state and coordination environment for iron ions in the glasses. The velocity scale was calibrated by using a spectrum of \( \alpha \)-Fe measured at room temperature. Isomer shifts (IS) were given with respect to \( \alpha \)-Fe. The temperature dependence of dc and ac susceptibilities was determined by using a Quantum Design superconducting quantum interference device magnetometer (model MPMS-XL). Specific heat was measured by a thermal relaxation method in zero magnetic field using a commercial calorimeter (Quantum Design, model PPMS).

III. \(^{57}\)Fe Mössbauer Spectroscopy

The \(^{57}\)Fe Mössbauer spectra for \( 33\mathrm{Fe}67\mathrm{PX} \) glasses are illustrated in Fig. 1. These spectra are explainable in terms of the superposition of paramagnetic doublets attributable to \( \mathrm{Fe}^{3+} \) and \( \mathrm{Fe}^{2+} \) ions. It is reasonable to presume that the absorption area ratio of paramagnetic doublets of \( \mathrm{Fe}^{2+} \) and \( \mathrm{Fe}^{3+} \) ions corresponds to their molar ratio. Table I summarizes the fraction of \( \mathrm{Fe}^{3+} \) in the total number of Fe ion, \( [\mathrm{Fe}^{3+}] / [\mathrm{Fetotal}] \), along with the values of Mössbauer parameters, i.e., IS and QS, are summarized in Table I for all the samples. These values were evaluated by fitting two symmetric Lorentzians to each of the paramagnetic doublets experimentally obtained. Irrespective of the value of \( x \), \( [\mathrm{Fe}^{3+}] / [\mathrm{Fetotal}] \) decreases with increasing the temperature of melting, \( T_m \). The result is in good agreement with those reported previously.\(^{24}\) A doublet of \( \mathrm{Fe}^{3+} \) ion is not observed in the spectra of glasses melted in a glassy carbon crucible. No systematic changes are found for IS and QS when \( x \) and \( T_m \) are varied. The values of IS and QS for the \( \mathrm{Fe}^{3+} \) and \( \mathrm{Fe}^{2+} \) ions \((IS=0.37–0.40 \text{ mm/s and } QS=0.83–0.90 \text{ mm/s for } \mathrm{Fe}^{2+}; IS=1.18–1.24 \text{ mm/s and } QS=2.17–2.29 \text{ mm/s for } \mathrm{Fe}^{3+}) \) indicate that both \( \mathrm{Fe}^{3+} \) and \( \mathrm{Fe}^{2+} \) ions mainly occupy octahedral sites surrounded by \( \mathrm{O}^{2-} \) ions in the glasses, although the presence of the \( \mathrm{Fe}^{3+} \) and \( \mathrm{Fe}^{2+} \) ions in the tetrahedral sites cannot be ruled out.\(^{24}\)

IV. MAGNETIC PROPERTIES

A. Temperature dependence of dc magnetic susceptibility

Figures 2(a) and 2(b) show the temperature dependence of dc susceptibility \( \chi(T) \) and its reciprocal \( \chi^{-1}(T) \), respectively, for \( x\mathrm{Fe}(100-x)\mathrm{PX}1200 \) glasses. The inset of Fig. 2(a) depicts an enlarged view of the low-temperature region between 2 and 10 K. The measurements were performed in both field-cooling (FC) and zero-field-cooling (ZFC) processes with a
magnetic field of \( H = 50 \) Oe applied. The \( \chi(T) \) curves of FC and ZFC are different from each other below the spin-freezing temperature, \( T_f \), at which the \( \chi(T) \) curve of ZFC exhibits a maximum. The spin-freezing temperature for all the glass samples is listed in Table I. The \( \chi(T) \) values of FC are kept almost constant below \( T_f \). The behavior is similar to that of typical spin glass. A linear relation between \( \chi^{-1}(T) \) and \( T \) at high temperatures reveals that these glasses are paramagnetic in the high-temperature region; the linear part is describable in terms of the following Curie-Weiss law

\[
\frac{1}{\chi} = \frac{3k_B(T - \theta_W)}{NM_B^f \mu_B^2},
\]

where \( \theta_W \) is the Weiss temperature, \( N \) is the number of magnetic ions per unit mass, \( \mu_B \) is the Bohr magneton, \( M_B \) is the effective number of Bohr magnetons, and \( k_B \) is the Boltzmann constant. The dashed lines in Fig. 2(b) present the fitting of Eq. (1) to the experimental data of \( \chi^{-1}(T) \) at temperatures from 100 to 300 K. The parameters of \( M_B \) and \( \theta_W \) evaluated by the fitting are also summarized in Table I, together with the theoretical effective number of Bohr magnetons, \( M_{B^{\text{theory}}} \), calculated by considering the valence states of iron ions and the spin moments for the high-spin states.

The value of \( M_B \) is slightly higher than or comparable to \( M_{B^{\text{theory}}} \), indicating that the orbital moments are substantially quenched by the crystal field. The negative values of \( \theta_W \) indicate that the antiferromagnetic interaction is dominant among magnetic moments in the present glasses. The varia-

FIG. 2. (Color online) Temperature dependence of (a) dc magnetic susceptibility \( \chi(T) \) and (b) its inverse \( \chi^{-1}(T) \) measured at \( H_{dc} = 50 \) Oe for the \( xFe(100-x)P1200 \) glasses with \( x = 33, 37, 40, \) and 45. The dashed lines denote the fit of Eq. (1) to the experimental data at high temperatures.
conventional spin glasses. One can see, however, that the
obtained for those glasses are also similar to those obtained for
spin-freezing temperature down. The solid line shows the best fit of Eq.
illustrates the relationship between maximum relaxation time \(\tau\) and
spin-freezing temperature \(T_c(f)\), i.e., the analysis of critical slowing
down. The inset shows the best fit of Eq. (2) to the experimental
data.

tions in \(T_c\) and \(\theta_0\) with the oxidation state of iron ions, as well as those with the glass composition, are discussed in Sec. VI.

B. Dynamic scaling analysis

Figure 3 depicts the temperature dependence of real part of zero-field-cooled ac susceptibility for 45Fe55P1200 glass. The amplitude of ac magnetic field was kept at 3 Oe and the ac frequency was varied from 0.3 to 1000 Hz. As can be seen in Fig. 3, the frequency-dependent spin-freezing temperature \(T_c(f)\), defined as a temperature at which the real part of ac susceptibility manifests a maximum, shifts to a higher-temperature side with an increase in \(f\). According to the dynamic scaling hypothesis, provided that this system exhibits a conventional critical slowing down toward the transition temperature \(T_c\), the temperature variation in relaxation time \(\tau = f^{-1}\) is described by

\[
\tau = \tau_0 \left( \frac{T_c(f) - T_c}{T_c} \right)^{-z\nu},
\]

where \(z\nu\) is the dynamic exponent and \(\tau_0\) is the microscopic relaxation time. In the present case, the best fitting of Eq. (2) to the experimental data yields \(z\nu=11.0\), \(T_c=7.5\) K, and \(\tau_0=2.1 \times 10^{-13}\) s, as shown in the inset of Fig. 3. The values of \(z\nu=11.0\) and \(2.1 \times 10^{-13}\) s are in good agreement with those reported for conventional atomic spin glasses.26,27 For 20Fe2O3, 80TeO2 glass, similar values, i.e., \(z\nu=10\) and \(\tau_0=1.0 \times 10^{-13}\) s, were obtained.9 The results of this analysis imply the occurrence of phase transition from a paramagnet to an atomic spin glass in the present iron phosphate glasses. The similar measurements and analyses have been performed for 33Fe67P1200, 33Fe67P1500, 33Fe67PC, 40Fe60PC, and 45Fe55P1500; the values of \(z\nu, T_c\), and \(\tau_0\) obtained by the analysis are summarized in Table II. The values of \(z\nu\) obtained for those glasses are also similar to those obtained for conventional spin glasses. One can see, however, that \(\tau_0\) varies in an enormous range over many orders of magnitude in a systematic way; with a decrease in \([\text{Fe}^{3+}] / [\text{Fe}_{\text{total}}]\), the value of \(\tau_0\) increases from \(\sim 10^{-13}\) to \(\sim 10^{-6}\) s. The value of \(\tau_0\) is too large and beyond the range of conventional atomic spin glasses. Not only the variation in \(\tau_0\) with \([\text{Fe}^{3+}] / [\text{Fe}_{\text{total}}]\) but also the surprisingly large value of \(\tau_0\) is discussed in terms of the effect of strong single-ion anisotropy of Fe3+ in Sec. VI.

C. Static scaling analysis of nonlinear susceptibility

In order to reinforce the presence of spin-glass transition in the iron phosphate glass system, the scaling analysis of static nonlinear susceptibility has been carried out for 45Fe55P1200 and 40Fe60PC glasses. We have analyzed the data concerning the temperature dependence of FC magnetization measured at various magnetic fields. Expanding \(M(T, H)\) in terms of odd powers of \(H\) in a temperature regime of \(T > T_c\) leads to

\[
M(T, H) = \chi_0(T) H - \chi_2(T) H^3 + \chi_4(T) H^5 - \ldots ,
\]

where \(\chi_0(T)\) is the linear susceptibility in the limit of \(H \rightarrow 0\). The static nonlinear susceptibility \(\chi_{NL}(T, H)\) is defined as follows:

\[
\chi_{NL}(T, H) = M(T, H) / H - \chi_0(T) = -\chi_2(T) H^2 + \chi_4(T) H^4 - \ldots .
\]

The temperature dependence of \(\chi_{NL}(T, H)\) for 45Fe55P1200 glass at varied magnetic fields is shown in the inset of Fig. 4, where \(\chi_0(T)\) is taken as the dc susceptibility measured at the smallest dc magnetic field in this experiment, i.e., 20 Oe. It is found that \(\chi_{NL}(T, H)\) exhibits a maximum at around \(T_c\). A similar behavior was also seen in insulating spin glasses such as \(\text{Zr}_{18}\text{Mn}_{82}\text{O}_{37}\).28 It is known that the scaling analyses developed for empirical description of paramagnet-ferromagnet phase transitions provide consistent results when applied to paramagnet-spin-glass transitions. The analysis has confirmed the scaling equation,29

\[
\chi_{NL} = -\beta^2 \Phi \left( \frac{H^2}{\beta^2 T_c^2} \right),
\]

where \(\tau = (T - T_c) / T_c\) is the reduced temperature and \(\beta\) and \(\gamma\) are the critical exponents. The universal curve resulting from the experimental data at \(T > T_c\) is depicted as log-log scale.

FIG. 3. Temperature dependence of real part of ac susceptibility \(\chi'(T)\) at \(H_{ac}=3\) Oe for 45Fe55P1200 glass. The frequency \(f\) is 0.3, 1, 3, 10, 30, 100, 300, and 1000 Hz (from top to bottom). The inset illustrates the relationship between maximum relaxation time \(\tau\) and spin-freezing temperature \(T_c(f)\), i.e., the analysis of critical slowing down. The solid line shows the best fit of Eq. (2) to the experimental data.
plots in Fig. 4. All the data can be suited on a single curve with $T_c = 7.8(1)$ K, $\beta = 0.9(1)$, and $\gamma = 3.6(2)$. In the case of 40Fe60PC glass, the values of $T_c = 2.7(1)$ K, $\beta = 0.9(1)$, and $\gamma = 3.5(3)$ produced the best scaling (data are not shown). The universal scaling curve covers several orders of magnitude on both ordinate and abscissa. The critical exponents obtained from the analysis are in good agreement with those reported for spin glasses with short-range interactions.28–32 At temperatures sufficiently higher than $T_c$ (lower left part of the curve), the slope approaches unity as expected. As $T$ approaches $T_c$ from the higher-temperature region (upper right part of the curve), the slope tends to be the proper asymptotic value $\beta/(\beta + \gamma)$.28–32 The static scaling analysis of nonlinear susceptibility provides additional evidence for the presence of spin-glass transition in the iron phosphate glasses.

D. ZFC memory effects

The magnetic aging and memory effects, which are characteristic of spin glasses, have been examined for 45Fe55P1200 glass to confirm the spin-glass behavior. The ZFC memory experiment proposed by Mathieu et al.2 has been performed. In this protocol, the system is cooled in zero magnetic field from a temperature higher than the transition temperature $T_b$ with or without an intermittent stop at a stopping temperature $T_s$ situated below $T_b$. The $\chi(T)$ curve is recorded during subsequent heating in a measuring magnetic field. Sasaki et al.33 demonstrated theoretically and experimentally that a memory is imprinted during the aging in the absence of magnetic field only for spin glasses and strongly interacting nanoparticles systems or superspin glasses, but not for noninteracting superparamagnets. Hence, observation of the memory effect warrants the cooperative freezing of spins.

In the present case, the glass sample was cooled at a rate of 0.2 K/min from a temperature well above $T_b = 7.8$ K to the stopping temperature $T_s$, which was lower than $T_b$, and was kept at $T_s$ for 3 h. Here, $T_c$ was selected to be 4, 5, and 6 K. After the aging at $T_s$ for 3 h, the glass sample was recooled to 3 K at a rate of 0.2 K/min. Subsequently, a magnetic field of 50 Oe was applied and $\chi(T_c, T)$ was measured on heating at a rate of 0.2 K/min. As a reference, $\chi_{ref}(T)$ was determined by measuring the temperature dependence of zero-field-cooled susceptibility without any intermittent stops. Figure 5 shows the results. The $\chi(T_c, T)$ curve coincides with the $\chi_{ref}(T)$ curve in a temperature range well below $T_c$. The $\chi(T_c, T)$ curves deviate downward from the $\chi_{ref}(T)$ curve as the temperature becomes close to $T_c$. As the temperature increases in a range above $T_c$, the $\chi(T_c, T)$ curves rapidly approach the $\chi_{ref}(T)$ curve, and eventually merge with the $\chi_{ref}(T)$. The difference between $\chi(T_c, T)$ and $\chi_{ref}(T)$ as a function of temperature is also illustrated in Fig. 5. The effect of aging at $T_c$ is reflected by the dip at around $T_c$. The experimental results definitely suggest that the magnetic phase of the present glass at very low temperatures is a spin glass.

V. MAGNETIC SPECIFIC HEAT

Magnetic specific heat, $C_{mag}$, has been explored for 33Fe67P1200, 33Fe67P1500, and 33Fe67PC to obtain more detailed information about the magnetic ordering in the present system. Here, we assume that the contribution of phonons to the specific heat of 33Fe67PX glasses with different molar fractions of Fe$^{3+}$ and Fe$^{2+}$ is identical to the sum of the specific heat of 33Ga$_2$O$_3$·67P$_2$O$_5$ (mol %) glass multiplied by [Fe$^{3+}$]/[Fe$_{total}$] and that of 33(2CaO)·67P$_2$O$_5$ (mol %) glass multiplied by (1-[Fe$^{3+}$]/[Fe$_{total}$]). It is reasonable to adopt the Ga$_2$O$_3$·P$_2$O$_5$ and CaO·P$_2$O$_5$ glasses for the estimation of phonon contribution to the specific heat of Fe$_2$O$_3$·P$_2$O$_5$ and FeO·P$_2$O$_5$ glasses, respectively, because the coordination environments for Ga$^{3+}$ and Ca$^{2+}$ ions are similar to those for Fe$^{3+}$ and Fe$^{2+}$ ions, respectively, in the phosphate glasses.34–36 The value of $C_{mag}$ was evaluated by subtracting...
the contribution of phonons from the total specific heat. In the inset of Fig. 6(a), $C_{\text{mag}}$ per 1 mol of iron ion is plotted as a function of $T$ in a temperature regime of 2 to 12 K. The temperature dependence of $C_{\text{mag}}$ for 33Fe67P1200, 33Fe67P1500, and 33Fe67PC shows very diffuse peaks at 8, 10, and 22 K, corresponding to 1.9$T_\text{f}$, 2.3$T_\text{f}$, and 10$T_\text{f}$, respectively. The broad maxima of $C_{\text{mag}}$ at temperatures much higher than $T_\text{f}$ are characteristic of spin glasses.\textsuperscript{37,38} An alternative view is that $C_{\text{mag}}$ is proportional to temperature with a positive intercept on the temperature axis [see the solid lines of the inset of Fig. 6(a)]. This behavior was also observed in conventional spin glasses.\textsuperscript{37,38} An alternative view is that $C_{\text{mag}}$ is proportional to $T^\alpha$ with $\alpha$=1.5–1.6 for the present glasses at low temperatures [see the dashed curves of Fig. 6(a)]. In general, $C_{\text{mag}} \propto T^{1.5}$ is expected from the spin-wave theory of ferromagnets. However, the $T^{1.5}$ dependence of $C_{\text{mag}}$ was reported for some magnets that exhibit spin-glass behavior such as Yb$_2$Mn$_3$O$_7$ and Na$_{0.70}$MnO$_{2.39-41}$. The quantity, $C_{\text{mag}}/T$, is plotted as a function of $T$ in Fig. 6(a). Figure 6(b) illustrates the temperature dependence of $\chi(T)$ and $\chi^{-1}(T)$ for the present glasses. The temperature dependence of $C_{\text{mag}}/T$ exhibits a peak at around $T_\text{f}$ (1.1$T_\text{f}$–1.2$T_\text{f}$). In a high-temperature regime, $C_{\text{mag}}/T$ is equal to zero and $\chi^{-1}(T)$ shows the Curie-Weiss behavior. With lowering the temperature, $\chi(T)$ begins to deviate from the Curie-Weiss law, accompanied by the onset of $C_{\text{mag}}/T$. This indicates that the short-range magnetic correlation emerges at temperatures higher by one order of magnitude than $T_\text{f}$, which is a clear signature of the magnetic frustration. At around 90 K, the magnetic entropy calculated by integrating $C_{\text{mag}}/T$ for $T$ reaches values between $R \ln 6$ and $R \ln 5$ expected from the degree of freedom for spins of Fe$^{3+}$ and Fe$^{2+}$, respectively, where $R$ is the gas constant.

VI. EFFECTS OF SINGLE-ION ANISOTROPY ON MAGNETIC PROPERTIES

As demonstrated above, the iron phosphate glasses exhibit transitions into spin-glass phases at low temperatures. We consider the effects of composition and valence state of iron ions on the magnetic properties. First, we discuss the magnetic parameters such as the spin-freezing temperature and Weiss temperature obtained by the temperature dependence of dc magnetic susceptibility (See Sec. IV A). Figures 7(a) and 7(b) illustrate contour plots of $\theta_{\text{W}}$ and $T_\text{f}$, respectively, on the $x$-[Fe$^{3+}$]/[Fe$_{\text{total}}$] planes. According to the high-temperature approximation of mean-field theory, $\theta_{\text{W}}$, a parameter reflecting the magnitude of the molecular field, is proportional to $J_{\text{eff}}N M^2_B$, where $J_{\text{eff}}$ is the effective exchange integral. In the present case, $x$ is directly related to $N$. The value of [Fe$^{3+}$]/[Fe$_{\text{total}}$] is relevant to $M^2_B$; the Fe$^{2+}$ and Fe$^{3+}$ ions have the electron configurations of $3d^6$ and $3d^5$, leading to $S=2$ and $S=5/2$ in their high-spin states, respectively. So, the mean value of $M_B$ increases with increasing
The value of \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) also affects the magnitude of \( J_{\text{eff}} \). The effective exchange integral of superexchange interaction via an oxide ion derived from the third-order perturbation is proportional to \( J_{\text{pd}}|t|^2/(\Delta E^2) \), where \( J_{\text{pd}} \) is the coupling constant of direct exchange interaction between the magnetic cations and the oxide ions, \( t \) is the transfer integral related to hopping of the electron between the \( 3d \) orbitals of magnetic cations and the \( 2p \) orbitals of oxide ion, and \( \Delta E \) is the excitation energy. These three parameters, \( J_{\text{pd}} \), \( t \), and \( \Delta E \), depend on the valence state of iron ions. Taking into account the fact that \( \text{Fe}^{3+} \)-based magnetic crystalline oxides usually have stronger superexchange interactions than \( \text{Fe}^{2+} \)-based ones, it is anticipated that in the present glasses the averaged value of \( [J_{\text{eff}}] \) becomes larger with an increase in \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \). The above discussion leads to the conclusion that the value of \( [\theta_0]/T_t \) becomes larger with increasing \( x \) and \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \). The similar tendency is anticipated for \( T_m \), although it is too difficult to formulate the spin-freezing temperature of spin glasses. As seen in Fig. 7(a), \( [\theta_0]/T_t \) exhibits an increase when \( x \) or \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) is higher; the higher values of \( [\theta_0]/T_t \) are found in upper right part of Fig. 7(a). On the other hand, the variation in \( T_m \) on the \( x-[\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) plane is rather different from that of \( [\theta_0]/T_t \) in Fig. 7(a). This is not in agreement with the above rough estimation.

Here we introduce the parameter, \( [\theta_0]/T_t \), in order to clarify another factor that affects the spin-freezing temperature. The contour plot of \( [\theta_0]/T_t \) on the \( x-[\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) plane is shown in Fig. 7(c). It should be noted that \( [\theta_0]/T_t \) approximately depends only on \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) and becomes smaller when \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) is decreased, indicating that the occurrence of magnetic transition tends to be favored when \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) becomes lower. This tendency is considered to be relevant to the difference in single-ion anisotropy between \( \text{Fe}^{2+} \) and \( \text{Fe}^{3+} \). Introducing spin-orbital coupling as second-order perturbation, magnetic ions such as \( \text{Fe}^{2+} \) and \( \text{Co}^{2+} \) have significant single-ion anisotropy even if they have nondegenerate ground states of electronic configuration due to the crystal-field effects. Assuming that the exchange interaction is isotropic, i.e., Heisenberg-type, the single-ion anisotropy is introduced into the Hamiltonian as follows:

\[
H = -\sum_{i,j} J_{ij} S_i \cdot S_j + \sum_i D_i (S_i^z)^2,
\]

where \( J_{ij} \) is the exchange coupling constant between the sites \( i \) and \( j \), \( S_i \) is the spin operator at the site \( i \), \( D_i \) is the single-ion anisotropy constant at the site \( i \), and \( S_i^z \) is the component of spin operator along the direction of the easy axis perpendicular to the easy plane at the site \( i \). The single-ion anisotropy term suppresses the fluctuation of magnetic moments caused by the thermal energy, so that the spin-freezing temperature is apt to be increased by the presence of the anisotropy. The effects of single-ion anisotropy are expected to be stronger for \( \text{Fe}^{2+} \) ion than for \( \text{Fe}^{3+} \) ion, although the existence of finite single-ion anisotropy effects is revealed even for S-state ions such as \( \text{Fe}^{3+} \) and \( \text{Gd}^{3+} \). Thus, from the point of view of fluctuation, the value of \( [\theta_0]/T_t \) decreases when \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) is lower.

On the other hand, the ratio of the absolute value of Weiss temperature to Néel temperature is regarded as an empirical measure of magnetic frustration for a number of geometrically frustrated antiferromagnets. In the present glasses, the value of \( [\theta_0]/T_t \) is sufficiently larger than unity, implying that the present system is magnetically frustrated. However, we must consider the effect of single-ion anisotropy on the magnetic frustration. It is thought that the single-ion anisotropy enhances the magnetic frustration since it becomes more difficult for the system to minimize the local exchange energies when the orientations of the magnetic moments are restricted. Besides, since the spatial distribution of \( \text{Fe}^{3+} \) and \( \text{Fe}^{2+} \) ions affects the strength of exchange interactions, the change in \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) can alter the degree of magnetic frustration in an intricate and, possibly, nonmonotonous way. Considering the fact that \( [\theta_0]/T_t \) decreases with a decrease in \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \), it is speculated that the single-ion anisotropy of \( \text{Fe}^{2+} \) has more significant influence on the fluctuation of magnetic moments rather than the magnetic frustration.

The suppression of spin fluctuation due to the single-ion anisotropy influences the spin dynamics, as discussed for molecular magnets. If we assume the uniaxial single-ion anisotropy for \( \text{Fe}^{2+} \) ion, the temperature dependence of microscopic relaxation time of \( \text{Fe}^{2+} \) ion is expected to be expressed as follows:

\[
\tau_0(T) = \tau_0^* \exp \left( \frac{D_c |S_z^c|^2}{k_B T} \right),
\]

where \( \tau_0^* \) is the relaxation time for spin flipping in the absence of energy barrier. Namely, the single-ion anisotropy is introduced as a thermal activation energy. For instance, crystalline lithium iron phosphate (LiFePO₄) has a single-ion anisotropy with an easy axis. The single-ion anisotropy leads to the slowing down in the flipping of magnetic moments. In the present case, the value of \( \tau_0 \) increases from \( 10^{-13} \) to \( 10^{-6} \) s with a decrease in \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) (see Table II). However, it is difficult to analyze the temperature dependence of \( \tau \) of 33Fe67PC and 40Fe60PC quantitatively using the equation derived by combining Eqs. (2) and (7), partly because \( D_c \) has a wide distribution depending on the \( \text{Fe}^{2+} \) site due to the random structure of glasses so that the temperature dependence of averaged value of \( \tau_0 \) shows complicated behavior. Thus, the dependences of \( [\theta_0]/T_t \) and \( \tau_0 \) on \( [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}] \) are just qualitatively explained by the single-ion anisotropy of \( \text{Fe}^{2+} \) ion.

The critical exponents of \( \beta=0.9(1) \) and \( \gamma=3.5(3) \) obtained in the static scaling analysis of nonlinear susceptibility for 40Fe60PC glass (see Sec. III C) are similar to those reported for many three-dimensional (3D) Heisenberg spin-glass systems with short-range interactions, rather than 3D Ising spin glass such as \( \text{Fe}_x\text{Mn}_{1-x}\text{TiO}_3 \), for which \( \beta=0.54 \) and \( \gamma=4.0 \). In the present system, each magnetic moment of \( \text{Fe}^{2+} \) should exhibit the Ising-like behavior due to the strong single-ion anisotropy, but the orientation of easy axis of single-ion anisotropy has a wide distribution due to the random structure of glasses. Hence, it does not seem that the present glasses, even when they contain only \( \text{Fe}^{2+} \) ions, are...
regarded as the simple Ising spin system. The Fe$^{2+}$-based glasses are interesting as a model for 3D spin-glass system with antiferromagnetic interactions and random anisotropy.

**VII. CONCLUSIONS**

The magnetic properties of mixed-valence iron phosphate glasses have been investigated. The scaling analyses of relaxation time and nonlinear susceptibility yield critical exponents similar to those reported for conventional spin glasses, indicating the presence of spin-glass transition at low temperatures. The observation of magnetic aging and memory effects reinforces the spin-glass nature of the present glasses. The experimental data of magnetic specific heat reveal that the deviation of magnetic susceptibility from the Curie-Weiss law corresponds to the emergence of short-range magnetic correlation. The single-ion anisotropy of iron ions plays an important role in both static and dynamic aspects of magnetic properties. In particular, the single-ion anisotropy leads to the suppression of spin fluctuation, resulting in the decrease in $\Delta H_0/T_i$ and increase in $\tau_0$ with a decrease in $[Fe^{3+}]$/$[Fe_{total}]$.

**ACKNOWLEDGMENTS**

The authors would like to thank M. Tosaki of Radioisotope Research Center, Kyoto University for the Mössbauer-effect measurements. The authors also thank M. Azuma and Y. Shimakawa of the Institute of Chemical Research, Kyoto University for specific-heat measurements. This research was partially supported by the Ministry of Education, Science, Sports and Culture, Grant-in-Aid for Scientific Research (B) (Grant No. 19360298) and Challenging Exploratory Research (Grant No. 21656163). One of authors (H.A.) thanks the Grant-in-Aid for Fellow (Grant No. 20-6726) from Japan Society for the Promotion of Science (JSPS).
