Kyoto University
EFFICACY OF A NOVEL INJECTABLE CEPHALOSPORIN, CEFCLIDIN®, ON THE EXPERIMENTAL COMPLICATED URINARY TRACT INFECTIONS WITH URINARY STONES CAUSED BY PSEUDOMONAS AERUGINOSA AND PROTEUS MIRABILIS

Masaru Satoh and Kei-ichi Munakata

From the Department of Microbiology, Tokyo Research Laboratories, Eisai Co., Ltd.

Hideo Takeuchi and Osamu Yoshida

From the Department of Urology, School of Medicine, Kyoto University

We evaluated the effects of a novel cephalosporin, cefclidin (CFCL) and imipenen (IPM), on the eradication of bacteria from the urine, bladder stones and the kidneys, and also on the prevention of the infection stone formations, in our polymicrobial urinary tract infection model of rats associated with bladder stones using IPM-sensitive or IPM-resistant Pseudomonas aeruginosa and Proteus mirabilis as a causative pathogen.

CFCL completely eradicated P. mirabilis from the urine and the stone in the short-term regimen (5 days). CFCL completely eradicated both IPM-sensitive P. aeruginosa and P. mirabilis from the urine, the stones and the kidneys as compared to IPM in the long-term regimen (11 days), reflecting the superior antibacterial activity of CFCL. CFCL also significantly prevented the development of infection stones as compared to IPM in the long-term regimen. There was no significant difference in the blood urea nitrogen (BUN) values between the CFCL or IPM-treated and the non-treated groups.

The cumulative recovery rate of unchanged CFCL reached 47.3% of the total dosage (20 mg/kg) within 8 hours.

Key words: Pseudomonas aeruginosa, Urinary tract infections

INTRODUCTION

Pseudomonas urinary tract infections associated with urinary stones, indwelling catheter and/or obstructive uropathy are well known refractory and resistant to various antipseudomonal chemotherapies. In terms of the bacteriological feature, most of Pseudomonas complicated urinary tract infections are noted to be polymicrobial infections. Accordingly, antipseudomonal agents with a broad spectrum are preferable in the management of Pseudomonas complicated urinary tract infections. Therefore, imipenem (IPM), which shows a very broad spectrum is one of the most useful antimicrobial agent in controlling Pseudomonas urinary tract infection1,2). However, emergence of resistant P. aeruginosa to IMP was recently noted on a patient with complicated urinary tract infections3,4). Some recent reports also indicated that resistance of P. aeruginosa to IPM was acquired in the course of the actual treatment4,5), probably due to the decrease in the permeability of IPM toward the outer membrane of P. aeruginosa6).

CFCL, a novel injectable cephalosporin, manifests a broad antibacterial spectrum and especially exhibits prominent activity toward various clinical isolates of P. aeruginosa including IPM-resistant P. aeruginosa7,8). Therefore, we evaluated the prospective usefulness of CFCL in the management of P. aeruginosa induced complicated urinary tract infections, using our polymicrobial urinary tract infection model associated with urinary stones9).
MATERIALS AND METHODS

Bacteria

Proteus mirabilis (E05106), IPM-sensitive (MIC of IPM < 3.13 μg/ml) Pseudomonas aeruginosa (E030033) and IPM-resistant (MIC of IPM > 6.25 μg/ml) Pseudomonas aeruginosa (E030400) were isolated from patients with urinary tract infections.

Antibiotics

CFCL was synthesized at Eisai Co., Ltd. and its purity was more than 98%. IPM preparation (Banyu Pham., Co., Ltd., Japan) was purchased.

Animals

Female Sprague Dawley strain rats (specific pathogen free, 7 weeks old, each weighing 180 to 220 g, Charles River Japan Inc.) were used in all experiments.

The experimental procedures for the preparation of our polymicrobial infection model in rats

The fundamental experimental procedures were conducted according to the method of Satoh et al. (1984). Namely, rats were intraperitoneally anesthetized with sodium pentobarbital. A sterile zinc ring (4 mm in diameter) was surgically implanted into the bladder followed by the administration of aminobenzyl-penicillin to prevent the infection associated with surgery.

Seven days after surgery, the first bacterium, P. mirabilis (10⁷ cfu/rat) was transurethrally inoculated through a polyethylene tube (PE-10), and then the second test bacterium, P. aeruginosa (10⁸ cfu/rat) was inoculated in the same manner 5 days after the first inoculation.

Three types of experiments were performed:

Experiment 1 [the short-term regimen for the IPM-sensitive P. aeruginosa (E030-033) plus P. mirabilis (E05106) infection]. The minimum inhibitory concentration (MIC) of CFCL for P. mirabilis (E05106) and P. aeruginosa (E030033) was 0.4 μg/ml and 0.8 μg/ml, respectively, and the MIC of IPM for P. mirabilis and P. aeruginosa was 6.25 μg/ml and 1.56 μg/ml, respectively. CFCL was administered intramuscularly twice a day at the dosage of 20 mg/kg for 5 days beginning from the 4th day after infection of P. aeruginosa. IPM was administered intramuscularly twice a day at the dosage of 10 mg/kg under the same condition.

Experiment 2 [the short-term regimen for the IPM resistant P. aeruginosa (E030-400) plus P. mirabilis (E05106) infection]. The MIC of CFCL and IPM for P. aeruginosa (E030400) was 0.2 μg/ml and 6.25 μg/ml, respectively. The antibiotics were administered under the same condition as described in experiment 1.

Experiment 3 [the long-term regimen for the IPM-sensitive P. aeruginosa (E030-033) plus P. mirabilis (E05106) infection]. The antibiotics were administered for 11 days under the same condition as described in experiment 1.

All the tested rats were killed to make the stipulated determinations 24 hours after the final dosing.

Bacteriological determinations

At the time of death, the bladder urine was aspirated with a tuberculin syringe, and then diluted with a sterile saline. Both kidneys were removed and homogenized. The bladder stones were removed from the bladder at autopsy and weighed, then immersed in a 70% alcohol solution for 10 minutes, followed by twice washing with a sterile saline and cultured after grinding them. Our preliminary examinations clarified that live bacteria on the surface of the bladder stone were eradicated by the immersion in 70% alcohol for 10 minutes, which had no effect on the live bacteria inside the bladder stone. The specimens were cultured after inoculation onto both BTB and NAC agar media (Eiken Co., Ltd., Japan).

Blood urea nitrogen (BUN) determinations

At the time of death, the blood specimens from the aorta abdominals were collected to determine the blood urea nitrogen (BUN) according to the method of Seligson11).

Determination of urinary recovery rates of antibiotics

The amounts of unchanged CFCL and
IPM in the urine were determined by the thin layer disc method using Escherichia coli E01174 and Bacillus subtilis ATCC 6633 as a test bacterium.

**RESULTS**

**Effects of CFCL and IPM on the polymicrobial infection of P. aeruginosa plus P. mirabilis in rats**

In experiment 1 (the short-term regimen for the IPM-sensitive P. aeruginosa plus P. mirabilis infection), CFCL completely eradicated P. mirabilis from the urine and the stones, and also P. aeruginosa from the stone. IPM eradicated P. aeruginosa from the stones, but could not eradicate P. mirabilis from the urine and the stones, and P. aeruginosa from the urine.

Both CFCL and IPM showed marked efficacy in preventing the development of infection bladder stones. There was no significant difference in BUN values or the incidence of kidney abscess between the treated and non-treated groups (Table 1).

In experiment 2 (the short-term regimen for the IPM-resistant P. aeruginosa plus P. mirabilis infection), CFCL more effectively eradicated IPM-resistant P. aeruginosa from the urine and the stone as compared to IPM, reflecting its superior in vitro antipseudomonal activity and CFCL also completely eradicated P. mirabilis from the urine and the stones. Furthermore, CFCL significantly prevented the development of infection bladder stones as compared to IPM. There was no significant difference in the incidence of abscess formation among the three groups and all the BUN values in the three groups were in the normal range (Table 2).

In experiment 3 (the long-term regimen...

Fig. 1. Urinary levels of CFCL and IPM in rats with infection stones caused by *P. mirabilis* plus *P. aeruginosa*. CFCL and IPM were administered intramuscularly 13 days after infection of *P. mirabilis* (8 days after infection of *P. aeruginosa*, CFCL; 20 mg/kg, IPM; 10 mg/kg).

For the IPM-sensitive *P. aeruginosa* plus *P. mirabilis* infection, CFCL completely eradicated both *P. aeruginosa* and *P. mirabilis* from the urine, the stones, and the kidneys. CFCL was significantly superior to IPM in the prevention of the development of infection bladder stones (Table 3). Kidney abscesses were observed in 6 of the 12 rats in the non-treated groups and in 1 of 8 rats in the IPM-treated groups. Meanwhile, none of the rats in the CFCL-treated group had kidney abscesses. The cumulative recovery rate of unchanged CFCL reached 47.3% of the total dosage (20 mg/
kg) within 8 hours, comparable to that of IPM (48.0%). Meanwhile, CFCL showed a urinary excretion pattern different from that of IPM, with a more prolonged urinary level (Fig. 1).

Emergence of resistant strains of *P. aeruginosa* toward CFCL and IPM during the present treatment was not observed.

**DISCUSSIONS**

We evaluated the efficacy of CFCL and IPM against the polymicrobial *Pseudomonas* urinary tract infections, a representative refractory infection, using our polymicrobial urinary tract infection model associated with urinary stones. The short-term regimen (5 days) with CFCL was insufficient to eradicate IPM-sensitive *P. aeruginosa* (MIC of CFCL: 0.8 μg/ml) from the urine as compared with the corresponding long-term regimen (11 days). This suggests that the long-term regimen should be used for the satisfactory management of *Pseudomonas* complicated urinary tract infections, even if a potent antipseudomonal agent such as CFCL is used. Meanwhile, CFCL more effectively eradicated IPM-resistant *P. aeruginosa* (MIC of CFCL: 0.2 μg/ml) from the urine and stones than IPM in the short-term regimen. This may be attributable to the difference in antipseudomonal activity and the urinary excretion pattern between CFCL and IPM.

Concerning the correlation between the MIC values and eradicative actions to *P. aeruginosa* from the urine, the kidney and the stones, an interesting finding has been reported; both the short-term and long-term regimen (11 days) with indicating MIC for the tested *P. aeruginosa* of 1.56 μg/ml were insufficient to eradicate *P. aeruginosa* from the urine, the stone and the kidney in the same experimental conditions. Similarly, the present study showed that IPM with an MIC of 1.56 μg/ml for *P. aeruginosa* was not sufficient for the eradication of *P. aeruginosa* in experimental 3 (the long-term regimen). Accordingly, the MIC values of a therapeutic agent toward *P. aeruginosa* must be below 0.8 μg/ml, in order to fulfill satisfactory eradication of *P. aeruginosa* from the urine, the kidney and associated infection stones.

In the present experiment, *Enterococcus faecalis* infections were observed in CFCL-treated, IPM-treated and non-treated groups, although, the rats had not been inoculated with *E. faecalis*. Our preliminary examinations clarified that these *E. faecalis* infections were inevitably induced by the transurethral cannulation of the polyethylene tube via the ascending route. Although IPM had potent antibacterial activity toward *E. faecalis*, *E. faecalis* could not be eradicated from the urine, the stones or the kidneys. The insufficient eradicative effects of IPM might be attributable to its rapid excretion from the urine.

Our present findings indicate that the associated *P. mirabilis* must primarily be eradicated for the complete eradication of *P. aeruginosa* because infection stones act as a sanctuary to hide bacteria from chemotherapy. Accordingly, it is basically important to remove the associated urinary stones from the urinary tract for the treatment of urinary tract infections accompanied with urinary stones. Recently, ultrasonic lithotripsy or extracorporeal shock wave lithotripsy has been widely used for the treatment of urinary stones. In lithotripsy regimen, the bacteria existing in the urinary stones are released and induce fever and bacteremia, so that the combination regimen of a powerful antibacterial agent such as CFCL and lithotripsy is strongly recommended as an intensive therapy in the management of *Pseudomonas* complicated urinary tract infections accompanied with urinary stones.
