Subcostal transabdominal incision with midline extension is excellent for removal of large renal or adrenal tumors, or bilateral or retroperitoneal tumors. This incision is simple and gives a wide surgical field without involving the pleural cavity. No troublesome complications resulting from this approach have occurred.

(Acta Urol. Jpn. 37: 1471-1474, 1991)

Key words: Renal tumor, Adrenal tumor, Retroperitoneal tumor, Subcostal transabdominal approach with midline extension

INTRODUCTION

Surgical approaches for tumors of the kidney, adrenal gland or retroperitoneal cavity do not always follow a common pattern. Up to now, three approaches for renal tumor and four adrenal or retroperitoneal tumors have generally been employed. All of these approaches have their merits and demerits. Although skilled surgeons can freely use these approaches, others generally practice their own favorite method. We report herein a method for subcostal transabdominal incision with midline extension for tumors of the kidney, adrenal gland or retroperitoneal cavity.

PATIENTS AND METHODS

Between January, 1980 and December, 1989, 27 patients, 16 males and 11 females, ranging in age from 14 to 79 years, with renal cancer, adrenal or retroperitoneal tumors were operated on using a subcostal transabdominal incision with midline ex-

ension.

Each patient was placed on the operating table in a supine position. The table was flexed slightly, or a thin cushion was inserted under the lumbar region to elevate the waist. An incision was made from the middle axillary line to the lateral margin of the opposite rectus muscle through the median line between the navel and the xiphoid process. In the case of bilateral adrenal tumors, a transverse incision was made from the tip of the eleventh rib to that of the opposite one. After dividing the skin, the peritoneal cavity was opened and the ligamentum teres was divided, followed by a midline extension to the xiphoid process (Fig. 1). The process was resected if the surgical field was insufficient, and a hook was placed at the margin of the subcostal arch. Thus a wide surgical field was provided.

RESULTS

The operation proceeded after completion of the incision, and the overall results

Fig. 1. Subcostal transabdominal approach with midline extension, in the case of a tumor located on the left side.

obtained were as follows. The operation time and intraoperative blood loss varied because of differences in the sites, sizes, stages and vascularity of the tumors, being 2 h 25 min~16 h 36 min (average 6 h 10 min) and 105~3,300 ml (average 832 ml), respectively. Three operations lasted over 12 h. Of these three, case 14 was bilateral adrenal pheochromocytoma and a pancreatic head tumor, for which a histological diagnosis of islet cell cancer was made. The patient was the father of the patient in case 20, who also had bilateral pheochromocytoma and a pancreatic tail tumor. The maximum blood loss during surgery was 3,300 ml in case 8, which was a recurrence of left adrenal pheochromocytoma. Paralytic ileus occurred in two cases, but this was alleviated within a few days. Wound healing was satisfactory. Resuture was not needed, although the wound partly gaped in two cases. Hypoalbuminemia due to lymphorrhea occurred in two cases.

With regard to diet, it took 3 to 20 days (average 6.4 days) until resumption of food intake after the operation. In case 14, 20 days passed until administration of food. Patients were bedridden from 4 to 40 days (average 9.9 days).

DISCUSSION

Existing approaches for renal or adrenal tumors are as follows;

1. Flank approach
2. Transabdominal approach (including

several variations)

3. Thoracoabdominal approach
4. Posterior approach

Of these approaches, the flank, transabdominal and thoracoabdominal ones are common, but the posterior approach is used exclusively for adrenal tumor.

The choice of incision for renal and adrenal tumors is determined by the patient's body habitus and by the position, mobility and number of kidney or adrenal glands involved. As the transabdominal approach has become commonly used, a subcostal transabdominal incision has been preferred over the last ten years at our clinic for renal, adrenal¹⁾ or retroperitoneal tumors. In the case of large renal or adrenal tumors, and bilateral adrenal or retroperitoneal tumors, the incision is followed by a midline extension to the xiphoid process. Isaka et al. recommended this approach for upper pole tumor of the right kidney, right adrenal tumor or inferior vena cava thrombus from renal cancer²⁾. The advantage of this incision is that a wide surgical field is provided without involving the pleural cavity. On the other hand, a midline incision was employed in only two cases because it was more difficult to perform on the lateral side of the tumor compared with the subcostal transabdominal incision. In the case of tumor thrombus beyond the level of the hepatic vein, the midline extension can easily be lengthened by median sternotomy in order to approach the supradiaphragmatic vena cava. In our patients, vena cavectomy and patch grafting of the vena cava were performed in case 3 and 4, respectively. The average number of days the patient was bedridden after treatment using a subcostal transabdominal incision with midline extension was 9.9 days, and that after a flank oblique incision was 5.8. The difference however, is not significant because the former was generally employed on large, bilateral or double tumors and others while the latter was used for small ones.

The patient data are briefly shown in Table 1, since they do not concern the

Table 1. Patients operated on using a subcostal transabdominal approach with midline extension

Case No.	Patient		Diagnosis	Operation time (h.m)	Blood loss (ml)	Weight of tumor (g)	Remarks

incision but rather the subsequent operations. Cases 14 and 20 were father and son. Although the incidence of familial pheochromocytoma with carcinoma arising from the pancreas islet is very low^{3,4)}, the existence of pancreatic tumor should be taken into consideration at the time of surgery. With regard to this approach, ileus usually becomes an issue. In this study, mild paralytic ileus occurred in two cases, and thus the incidence was lower than expected. Hypoalbuminemia occurred in case 8, and was not alleviated before the patient's discharge.

上腹部横切開に垂直切開を加えた切開法は腎腫瘍、副腎腫瘍あるいは後腹膜腫瘍の手術の際に用いる胸膜を開くことなく広い術野が得られるという利点があった。新大泌尿器科では1980~1989年の10年間に27例に対してこの切開法を用いた。この方法は腹腔を経由す

るので、後腹膜腔から入る方法に比し合併症が多いように思われたが、2例に軽い麻痺性イレウスが発生したのみであった。また、再手術を要するような重篤な合併症は生じなかった。
