Abstract

Recently, insulin signaling has been highlighted in the pathology of Alzheimer’s disease (AD). Although the association between insulin signaling and Tau pathology has been investigated in several studies [1-3], the interaction between insulin signaling and Presenilin 1 (PS1), a key molecule of Amyloid β (Aβ) pathology, has not been elucidated so far. In this study, we demonstrated that insulin inhibited PS1 phosphorylation at serine residues (serine 353, 357) via phosphatidylinositol 3-kinase (PI3K)/Akt signal pathway and strengthened the trimeric complex of PS1/N-cadherin/β-catenin, consequently relocating PS1 to the cell surface. Since our recent report suggests that PS1/N-cadherin/β-catenin complex regulates Aβ production [4], it is likely that insulin signaling affects Aβ pathology by regulating PS1 localization.

Introduction

Alzheimer’s disease (AD) is pathologically characterized by amyloid plaques and neurofibrillary tangles (NFTs). Amyloid plaques are composed of amyloid β peptides (Aβ), which are derived from the amyloid precursor protein (APP) via proteolytic cleavage, by γ-secretase [5]. γ-Secretase is an enzymatic complex composed of at least four proteins – Presenelin 1 or Presenelin 2 (PS1 or PS2), Nicastrin, Pen 2 and Aph 1 – with Presenilin representing the catalytic core [6-8]. On the other hand, NFTs are characterized by the accumulation of hyperphosphorylated Tau in neurons [9]. One of the candidates which phosphorylates Tau is Glycogen synthase kinase 3 β (GSK3β) [10]. GSK3β is a serine/threonine protein kinase, originally known to inactivate glycogen synthesis. GSK3β, an important player in insulin signal cascade [11], is negatively regulated by insulin.

GSK3β also has a wide variety of substrates, other than glycogen synthase, and is expressed in various tissues, with the highest level in the brain. Expression of GSK3β in the brain is considered to be involved in
abnormal Tau phosphorylation in NFTs [9]. Interestingly, PS1 is also shown to be an unprimed substrate of GSK3β [12], phosphorylated at the serine 353 and 357 residues in the loop domain [13]. Therefore, it is intriguing to investigate the influence of insulin on the function of PS1 through GSK3β, which could connect two major pathological hallmarks of AD, namely Aβ and NFTs.

A potential link between type 2 diabetes and AD has been suggested epidemiologically, clinically and experimentally [14-16], indicating the involvement of perturbed insulin signaling in AD pathogenesis. Interestingly, insulin and the insulin-sensitizing drug have shown to improve cognitive performance in mouse models of AD, as well as in patients with early AD [17-19]. Although many reports suggest that perturbed insulin signaling could contribute to the AD pathogenesis, direct interactions between insulin signaling and PS1 have not been elucidated so far.

Here, we demonstrate that insulin inhibits PS1 phosphorylation and potentiates PS1/N-cadherin/β-catenin complex formation at the cell membrane, subsequently redistributing PS1 to the cell surface via PI3K/Akt signal pathway. Our findings clearly indicate that PS1 is functionally modulated by insulin signaling, thus providing a novel link between glucose metabolism and AD pathogenesis.
Material and methods

Plasmid constructs

The pcDNA3.1-hIR (human Insulin Receptor) construct was a kind gift from Dr. Ikeuchi (Niigata University, Japan) [20].

Cell culture and transfection

For the establishment of cell lines which stably express hIR (Supplemental Fig. 1), SH-SY5Y (derived from human neuroblastoma) cells were transfected with pcDNA3.1-hIR, using a TransFectin reagent (Bio-Rad) and selected by 300 µg/ml G418 solution (nacalai tesque, Japan). Primary neurons were obtained from the cerebral cortices of fetal mice (14-16 days’ gestation) and cultured with Neurobasal medium containing B-27 supplements and 0.5 mM L-glutamine (all reagents purchased from Invitrogen). After 7 days’ culture, cells were used in the experiment.

Antibodies and chemical reagents

Mouse monoclonal anti-IR was from Neo Markers (Fremont, CA). Rabbit polyclonal anti-Akt, phospho-Akt (S473), phospho-GSK3β (S9) and mouse monoclonal anti-phospho-β-catenin antibodies were from Cell Signaling Technology. Mouse monoclonal anti-GSK3β, N-cadherin and β-catenin antibodies were from BD Transduction Laboratories. Mouse monoclonal anti-phospho-serine, β-actin and Aβ (6E10) antibodies were from SIGMA. Rabbit polyclonal anti-PS1 NTF, goat polyclonal PS1 CTF and phospho-PS1 (S353/357) antibodies were from Santa Cruz. Alexa Fluor 546 anti-mouse IgG and Alexa Fluor 488 anti-goat IgG were obtained from Molecular Probes. Insulin solution was from SIGMA and DMSO was from nacalai tesque.

Western blotting and Immunoprecipitation
Preparation of protein samples, Western blotting and immunoprecipitation analysis were carried out as described previously [21].

**Immunostaining**

Preparation of cell samples and immunostaining analysis was carried out as described previously [22]. The samples were examined using a laser confocal scanning microscope, LSM 510 Pascal (Zeiss).

**Aβ application**

Synthetic Aβ 1-40, 1-42 and control reverse peptides were obtained from Bachem. Each peptide was dissolved in 100% dimethyl sulfoxide (DMSO), at a concentration of 1 mM Aβ solution and aliquots were prepared, which were either used fresh or fresh-frozen, and stored at -80°C until use. Aβ solutions were added to Opti-MEM, to give a final concentration of 1 μM Aβ 1-40 or 100 nM Aβ 1-42, respectively. Immediately, SH-SY5Y wt IR cells or primary neurons were pre-incubated in the Aβ containing media for 30 min at 37°C. After pre-incubation, the cells were stimulated by 50 nM insulin for 30 min, in the presence of Aβ (Schematic presentation of this experiment is described in Supplemental Fig. 3A). Characterization of the Aβ species in this experiment was analyzed by Tricine-SDS-PAGE (Supplemental Fig. 3B).

**Biotinylation of cell surface proteins**

Preparation of cell samples and biotinylation analysis were carried out as described previously [22]. Precipitated biotinylated proteins were then subjected to Western blotting analysis.

**Statistical analysis**
All values are given in means ± SE. Comparisons were performed using an unpaired Student’s t-test. For comparison of multiparametric analysis, one-way factorial ANOVA followed by post hoc analysis by Fisher’s PLSD was used. \( p < 0.05 \) was considered to indicate a significant difference. \( n = 4 \) indicated four independent experiments.
**Results**

*Insulin signaling inhibited PS1 phosphorylation.*

To investigate the possibility of direct influence of insulin signaling on PS1, we examined whether activated PI3K/Akt signaling by insulin inhibits GSK3β activity as well as PS1 phosphorylation. In SH-SY5Y wt IR cells, PI3K/Akt pathway was activated by insulin, leading to phosphorylation of GSK3β at serine 9 (Fig. 1A, 2nd and 4th rows). The inhibition of GSK3β activity was confirmed by the detection of phospho- and total levels of β-catenin (Fig. 1A, 6th and 7th rows) which is a substrate for GSK3β-mediated phosphorylation, since GSK3β-mediated phosphorylation destabilizes β-catenin by promoting proteasomal degradation [23]. Accordingly, insulin significantly reduced the level of phosphorylated PS1 in serine 353 and 357 residues (Fig. 1B, D). This result was confirmed by immunoprecipitation assay (Fig. 1C), and immunostaining with phospho-specific anti-PS1 antibody clearly demonstrated that insulin treatment markedly reduced PS1 phosphorylation in the cells (Fig. 1E-H).

*Insulin signaling regulates the subcellular localization of PS1.*

We previously reported that PS1 phosphorylation at serine 353 and 357 affects its localization. Phosphorylation at serine 353 and 357 inhibits PS1 binding to N-cadherin/β-catenin complex [22]. Since insulin signaling inhibited PS1 phosphorylation, we assumed that insulin would in turn redistribute PS1 to the cell surface. We examined the effect of insulin on PS1/N-cadherin/β-catenin complex by immunoprecipitation assay. Insulin treatment dose-dependently increased the binding of PS1 to N-cadherin, as well as to β-catenin (Fig. 2A, 1st and 2nd rows) in SH-SY5Y wt IR cells (relative phosphorylation ratio of p-GSK3β S9/ GSK3β is described in Supplemental Fig. 2A). This result was also confirmed in mouse cortex primary neurons (Fig. 2B, 2nd and 3rd lane). Several downstream pathways are involved in insulin signaling [24, 25]. To verify that GSK3β,
which is an immediate downstream target of PI3K/Akt pathway, downregulates the association of PS1 and N-cadherin/β-catenin complex, SH-SY5Y wt IR cells were pre-treated with Akt inhibitors (Akt inhibitor IV, X) before insulin treatment. Although the treatment with both inhibitors reduced the binding of PS1 to N-cadherin/β-catenin (Fig. 2C), quantitative analysis revealed that Akt inhibitor IV was less effective in phosphorylation of GSK3β, compared to Akt inhibitor X (Fig. 2D). On the other hand, we demonstrated that GSK3β inhibitors strengthened the complex as well as insulin in primary neurons (Fig. 2B, 4th and 5th lanes).

We have previously reported that physical interaction between PS1 and N-cadherin/β-catenin plays an important role in cell surface expression of PS1/γ-secretase [22]. Therefore, we examined the expression level of cell surface PS1 in the presence of insulin by biotinylation assay. As expected, the cell surface PS1 level in insulin-treated cells was higher than that in non-treated ones, confirming that inhibition of GSK3β by insulin redistributes PS1 to the cell surface (Fig. 2E, top row, right lane).

**Aβ application affects the state of PS1 phosphorylation and its complex formation.**

Several reports have suggested that Aβ can interfere with insulin signaling [26-28]. Since insulin signaling could decrease the phosphorylation state of PS1, we treated cells with the medium containing 1 µM Aβ40 or 100 nM Aβ42 and examined the state of PS1/N-cadherin/β-catenin complex, as well as PS1 phosphorylation. Aβ species in the media were characterized by Tricine-SDS-PAGE (Supplemental Fig. 3B). Both media contained similar species including monomer and SDS-resistant oligomers – dimer, trimer, tetramer and high molecular weight oligomers. Interestingly, treatment with the medium containing either Aβ40 or Aβ42 increased the level of phosphorylated PS1 (Fig. 3A, top row, 1st and 2nd lanes), suggesting the up-regulation of GSK3β activity (Fig. 3A, 3rd row, 1st and 2nd lanes, Fig. 3B). Moreover, the interaction of PS1/N-cadherin/β-catenin was reduced in neurons treated with Aβ-containing medium (Fig. 3C, 1st and 2nd rows, 2nd and 3rd lanes),
compared to reverse Aβ-containing medium (Fig. 3C, 4th lane), indicating that soluble forms of Aβ can enhance PS1 phosphorylation and inhibit the PS1/N-cadherin/β-catenin interaction.
Discussion

Several lines of evidence suggested a potential link between type 2 diabetes and AD. So far, the causal relationship between them has been investigated by two distinct approaches: the modulation of Tau phosphorylation by GSK3β activity, and Aβ metabolism. In the former, loss of insulin-mediated activation of PI3K and subsequent reduction of phosphorylation of Akt and GSK3β are reported to result in a substantial increase in levels of phosphorylated Tau in the brains of neuron specific IR knockout mice [3]. Abnormal increase in the GSK3β level and activity is actually associated with AD pathophysiology [29]. As for the latter, since it is known that Aβ is resolved by Insulin-degrading enzyme (IDE), some researchers hypothesize that higher insulin levels in a diabetic condition can induce Aβ accumulation by directly competing with Aβ for IDE, thereby limiting Aβ degradation [30, 31]. In spite of mounting evidence that insulin signaling dysfunction or insulin resistance are implicated in AD pathophysiology, it still remains largely unknown how two pathological hallmarks – Amyloid and Tau – are causally related to each other via insulin signaling.

In the present study, we have shown for the first time that insulin-mediated PI3K/Akt signaling decreases the phosphorylation of PS1 and enhances PS1/N-cadherin/β-catenin interaction via inhibition of GSK3β activity (Fig. 1 and 2). As shown in Figure 3D, insulin treatment inactivates GSK3β, thereby blocking its activity on PS1 phosphorylation. This tightens the binding of PS1 to N-cadherin/β-catenin complex, which results in relocating PS1 to the cell surface. In contrast, if this pathway fails to phosphorylate GSK3β due to either signaling dysfunction or insulin resistance, GSK3β in an active form tends to phosphorylate PS1, which has less ability to form the complex. Since the total β-catenin level is affected by the inhibition of GSK3β, the increase of PS1/β-catenin association could be attributed to the elevation of the total β-catenin level. However, the total N-cadherin level did not change before and after insulin treatment (Fig. 2) thus, leading us to conclude that insulin increased the association of PS1 to N-cadherin/β-catenin complex.
In our study, acute application of Aβ was sufficient to impair the interaction of PS1 and N-cadherin/β-catenin, suggesting the possibility that an ample amount of Aβ could lead to aberrant phosphorylation of PS1 in AD brains, via reduction of insulin signaling (Fig. 3A-C). The media used in our study contained monomers and various SDS-resistant Aβ oligomer species, which were derived from synthetic Aβ (Supplemental Fig. 3). Since several reports suggest that Aβ oligomers play an important role on insulin signaling [26-28], we assume that the total effect of the Aβ mixture containing these oligomers has an impact on this signaling as well as on PS1 phosphorylation. In our recent report, we demonstrated that disruption of PS1/N-cadherin/β-catenin complex impairs Aβ production but increases the Aβ 42/40 ratio [4]. Therefore, we postulate that perturbed insulin signaling could play a pivotal role in relocating PS1 to the cell surface, which in turn may have an impact on Aβ production and Aβ 42/40 ratio.

In relevant literature, neuronal insulin receptor-deficient mice (NIRKO) revealed a great increase in the phosphorylation of Tau protein [3]. The decreased phosphorylation of GSK3β observed in these mice results in an increased GSK3β activity and may cause the increase in Tau phosphorylation. However, these mice did not show any special learning deficits or long-term memory disturbance, suggesting that the mere lack of the IR is not sufficient to cause AD-like symptoms. Hence, we hypothesize that molecules downstream from the IR might be involved in actual AD brains, with PS1 being a possible target for connecting two seemingly independent pathological features – Amyloid and Tau pathologies. Further studies are required to clarify the functional interaction between PS1 and insulin signaling in vivo models. Our findings for the first time demonstrated that insulin has a potent effect on the localization of PS1 in neuronal cells. Whether these phenomena are actually involved in the pathology of sporadic AD cases should be elucidated in future studies. Uncovering the mechanism that links diabetes and AD will be important, as it may provide a therapeutic target.
