Lines pinning lines*

Boris Aronov$^1$ Otfried Cheong$^2$ Xavier Goaoc$^3$

1 Introduction

A line transversal to a family of convex objects in $\mathbb{R}^d$ is a line intersecting each member of the family. There is a rich theory of geometric transversals, see for instance the surveys of Danzer et al. [3], Eckhoff [4], Goodman et al. [5] and Wenger [7].

A classic result is Hadwiger's transversal theorem: a family $\mathcal{F}$ of (pairwise) disjoint compact convex sets in the plane has a line transversal if and only if there is an ordering of $\mathcal{F}$ such that each triple has a line transversal consistent with that ordering. The idea of Hadwiger's original proof is to uniformly shrink the sets until a triple has a unique transversal $\ell$. The line $\ell$ is then necessarily an isolated transversal of the triple, that is, any perturbation of $\ell$ will miss a member of the triple.

Cheong et al. [2] recently proved a similar Hadwiger-type theorem: a family $\mathcal{F}$ of (pairwise) disjoint unit balls in $\mathbb{R}^d$ has a line transversal if and only if there is an ordering of $\mathcal{F}$ such that each $2d$-tuple has a line transversal consistent with that ordering. Again, the idea of the proof is to shrink the balls uniformly until some $2d$-tuple has a unique transversal.

We call an isolated transversal $\ell$ to a family $\mathcal{F}$ a pinned transversal, and the family $\mathcal{F}$ a pinning of $\ell$. If $\mathcal{F}$ pins $\ell$ and no proper subset of $\mathcal{F}$ does, then $\mathcal{F}$ is a minimal pinning of $\ell$. A minimal pinning by compact convex figures in the plane consists of exactly three objects; we say that convex figures have pinning number three. Cheong et al. [2] show that disjoint unit balls have pinning number $2d - 1$, this result can be generalized to disjoint balls of arbitrary radius [1].

The existence of a bounded pinning number can be interpreted as a Helly-type theorem: a family $\mathcal{F}$ of disjoint balls does not pin a line $\ell$ if and only if every subfamily of size at most $2d - 1$ does not pin $\ell$. The version of Hadwiger's theorem for disjoint balls is rather exceptional in the sense that no such generalization holds for line transversals to disjoint convex sets in dimension greater than two, not even for disjoint translates of a convex set [6]. In particular, there are ordered families $\mathcal{F}$ of $n$ convex polytopes in $\mathbb{R}^3$

without a line transversal, but such that any subfamily of size $n-1$ has a line transversal consistent with the ordering.

In this paper, we show that, nevertheless, convex polytopes in $\mathbb{R}^3$ have bounded pinning number, at least under a mild assumption: If a family $\mathcal{F}$ of convex polytopes pins a line $\ell$ and $\ell$ touches each polytope in an edge, then there is a subfamily $\mathcal{F}' \subset \mathcal{F}$ of at most eight polytopes that already pins $\ell$.

This implies that a bounded pinning number is a strictly weaker property than a Hadwiger-type theorem for transversals: while the existence of a line transversal is not necessarily determined by a bounded subfamily, locally this is the case. It will be interesting to see how far the bounded pinning number generalizes. So far, we know of no class of convex objects that does not have a bounded pinning number.

The assumption that $\ell$ may not touch a polytope $P \in \mathcal{F}$ in a facet is necessary for our arguments, since we reduce the family of polytopes to a family of oriented lines, as follows:

Given two non-parallel oriented lines $\ell_1$ and $\ell_2$ with direction vectors $d_1$ and $d_2$, we say that $\ell_2$ passes to the right of $\ell_1$ if $\ell_2$ can be translated by a positive multiple of $d_1 \times d_2$ to meet $\ell_1$.

Consider a line $\ell_0$ that is pinned by a family of convex polytopes. Any polytope whose interior intersects $\ell_0$ cannot contribute to the pinning, and so we can assume that all polytopes are tangent to $\ell_0$. The restriction we will make in this paper is that we assume that $\ell_0$ touches each polytope $P$ in an edge $e$. This means that we can orient the supporting line $g$ of $e$ in such a way that for lines $\ell$ in a neighborhood of $\ell_0$, $\ell$ intersects $P$ if and only if $\ell$ meets $g$ or passes to the right of $g$.

This observation fails if we allow $\ell_0$ to touch $P$ in a facet. On the other hand, touching in a vertex can be handled by considering two edges, as long as $\ell_0$ is not coplanar with a facet incident to the vertex.

The observation allows us to discard the original family of convex polytopes, and to speak about lines pinned by a family $\mathcal{F}$ of oriented lines. Formally, a line $\ell_0$ is pinned by a family $\mathcal{F}$ of oriented lines if there is a neighborhood $N$ of $\ell_0$, such that for every $\ell' \neq \ell_0$ in $N$, there is a line $g \in \mathcal{F}$ such that $\ell'$ passes to the left of $g$.

We will exclude families $\mathcal{F}$ where two lines of $\mathcal{F}$ are simultaneously concurrent and coplanar with $\ell_0$. (Indeed, this cannot happen if the lines come from edges of polytopes pinning $\ell_0$.)

## 2 Preliminaries

Without loss of generality, we identify $\ell_0$ with the positively oriented $z$-axis. We are interested in lines in a neighborhood of $\ell_0$. Let $\mathcal{L}$ denote the set of lines (all our lines are oriented) whose direction makes positive dot-product with $(0,0,1)$. Any line $\ell \in \mathcal{L}$ intersects the two planes $z = 0$ and $z = 1$, and $\mathcal{L}$ is homeomorphic to $\mathbb{R}^4$, where $u = (u_1, u_2, u_3, u_4) \in \mathbb{R}^4$ corresponds to the line $\ell(u)$ passing through $(u_1, u_2, 0)$ and $(u_3, u_4, 1)$. We have $\ell_0 = \ell(0)$, and any sufficiently small neighborhood of $\ell_0$ corresponds to a neighborhood of 0 in $\mathbb{R}^4$.

Consider now the family $\mathcal{C}$ of (oriented) lines crossing $\ell_0$, that is, meeting $\ell_0$ without being parallel to it. A line $g \in \mathcal{C}$ meets $\ell_0$ in a point $(0, 0, \lambda)$, makes a slope $\delta$ with the plane
$z = \lambda$, and its projection on the $xy$-plane makes an angle $\alpha$ with the positive $x$-axis. Let $g(\lambda, \alpha, \delta)$ be this line. It passes through the points $(0, 0, \lambda)$ and then $(\cos \alpha, \sin \alpha, \lambda + \delta)$.

For a line $g = g(\lambda, \alpha, \delta) \in \mathcal{C}$, we define the function $\sigma_g : \mathbb{R}^4 \rightarrow \mathbb{R}$ as

$$\sigma_g(u) := \begin{vmatrix} u_1 & u_3 & 0 & \cos \alpha \\ u_2 & u_4 & 0 & \sin \alpha \\ 0 & 1 & \lambda & \lambda + \delta \\ 1 & 1 & 1 & 1 \end{vmatrix} = \delta (u_2 u_3 - u_1 u_4) + \eta(\lambda, \alpha) \cdot u,$$

where

$$\eta(\lambda, \alpha) := \begin{pmatrix} (1 - \lambda) \sin \alpha \\ -(1 - \lambda) \cos \alpha \\ \lambda \sin \alpha \\ -\lambda \cos \alpha \end{pmatrix}.$$  

We note that $\sigma_g(u)$ is zero if $\ell(u)$ meets $g$, positive if $\ell(u)$ passes to the right of $g$, and negative if $\ell(u)$ passes to the left of $g$.

The function $\sigma_g$ is quadratic, so the set $S_g := \{u \in \mathbb{R}^4 \mid \sigma_g(u) = 0\} \subset \mathbb{R}^4$ is a quadric through the origin. However, when $g$ is parallel to the $xy$-plane, then $\delta = 0$, the quadratic term vanishes, and $S_g$ becomes the hyperplane $\eta(\lambda, \alpha) \cdot u = 0$ through the origin. By the above, the line $\ell(u)$ meets $g$ if and only if $u \in S_g$.

We can now define $\mathcal{U}_g := \{u \in \mathbb{R}^4 \mid \sigma_g(u) \geq 0\} \subset \mathbb{R}^4$. The volume $\mathcal{U}_g$ is bounded by $S_g$. The line $\ell_0$ is pinned by a family $\mathcal{F} \subset \mathcal{C}$ if and only if $N \cap \bigcap_{g \in \mathcal{F}} \mathcal{U}_g = \{0\}$ for some neighborhood $N$ of the origin 0.

Let $\mathcal{C}(\lambda, \alpha) := \{g(\lambda, \alpha, \delta) \mid \delta \in \mathbb{R}\} \subset \mathcal{C}$, and consider $g \in \mathcal{C}(\lambda, \alpha)$. The function $\sigma_g$ is smooth and its gradient at the origin is $\eta(\lambda, \alpha)$. The vector $\eta(\lambda, \alpha)$ is therefore the normal to the surface $S_g$ at the origin, pointing into the interior of $\mathcal{U}_g$. Since $\eta(g) := \eta(\lambda, \alpha)$ does not depend on $\delta$, all surfaces $S_g$ for lines $g \in \mathcal{C}(\lambda, \alpha)$ share the same tangent hyperplane $h(\lambda, \alpha) = \{u \in \mathbb{R}^4 \mid \eta(\lambda, \alpha) \cdot u = 0\}$ at the origin. The line $g^+(\lambda, \alpha) := g(\lambda, \alpha, 0)$ is the only line $g \in \mathcal{C}(\lambda, \alpha)$ for which $S_g$ coincides with $h(\lambda, \alpha)$.

Given a family $\mathcal{F} \subset \mathcal{C}$, we call $\mathcal{F}$ generic if the normal vectors $\eta_g$ corresponding to every four lines in $\mathcal{F}$ are linearly independent.

For families of lines all orthogonal to $\ell_0$, this is a natural definition: If $\mathcal{F}$ is generic, then the common intersection of any four hyperplanes $S_g$ is exactly the origin $\{0\}$. This is the same as saying that any four lines in $\mathcal{F}$ have no infinite family of transversals (in fact, they have only the single transversal $\ell_0$).

## 3 Pinning by orthogonal lines

In this section, we assume that $\mathcal{F}$ is a family of (oriented) lines all orthogonal to the line $\ell_0$. This implies that the surfaces $S_g$ are hyperplanes through the origin, and the volumes $\mathcal{U}_g$ are half-spaces. We can therefore use Helly’s dimensional theorem to obtain our main result:

**Theorem 1.** If a line $\ell_0$ is pinned by a family $\mathcal{F}$ of oriented lines all orthogonal to $\ell_0$, then there is a subfamily $\mathcal{F}' \subset \mathcal{F}$ of size at most eight that already pins $\ell_0$. Furthermore, if $\mathcal{F}$ is generic, then the size of $\mathcal{F}'$ is at most five.
Proof. The assumption of pinning implies $\bigcap_{g \in \mathcal{F}} \mathcal{U}_g = \{0\}$. By the dimensional Helly theorem, the intersection of $n$ convex sets in $\mathbb{R}^4$ is a single point if and only if they all intersect and eight of them intersect in a single point. This implies that there is a subfamily $\mathcal{F}'$ of eight oriented lines that already pin $\ell_0$.

Assume now that $\mathcal{F}$ is generic, and for each $g \in \mathcal{F}$, let the open halfspace $\mathcal{U}'_g$ be the interior of $\mathcal{U}_g$. We have $\bigcap_{g \in \mathcal{F}} \mathcal{U}'_g = \emptyset$, and so by Helly's theorem there is subfamily $\mathcal{F}' \subset \mathcal{F}$ of at most five halfspaces with $\bigcap_{g \in \mathcal{F}'} \mathcal{U}'_g = \emptyset$. Since any four normals are linearly independent, this implies that $\bigcap_{g \in \mathcal{F}} \mathcal{U}_g = \{0\}$, proving the theorem. 

The number eight in the theorem is not tight, since we excluded pairs of lines that are concurrent and simultaneously coplanar with $\ell_0$. In the full paper, we characterize all possible configurations.

4 Pinning by generic lines

We will start by discussing what it means for a family $\mathcal{F} \subset \mathcal{C}$ to be generic.

Consider three lines $g_1, g_2, g_3 \in \mathcal{C}$ with $g_i \in \mathcal{C}(\lambda_i, \alpha_i)$. If all three lie in a common plane then $\alpha_1 = \alpha_2 = \alpha_3$. In this case, any line lying in this common plane will intersect all three lines, and the intersection $S_{g_1} \cap S_{g_2} \cap S_{g_3}$ is a two-plane. In all other cases, $S_{g_1} \cap S_{g_2} \cap S_{g_3}$ is a one-dimensional curve, corresponding to lines in $\mathcal{L}$ that meet all three lines $g_1, g_2, g_3$. The union of these transversal lines is a doubly-ruled quadric $\mathcal{B}(g_1, g_2, g_3)$. The first family of rulings consists of the transversals to $g_1, g_2, g_3$, the second family of rulings contains the lines $g_1, g_2, g_3$. The line $\ell_0$ is a line of the first family. For every point $(0, 0, \lambda) \in \ell_0$, there is exactly one line from the second family of rulings through $(0, 0, \lambda)$. This means that there is an $\alpha$ and a $\delta$ such that $g(\lambda, \alpha, \delta)$ is contained in $\mathcal{B}(g_1, g_2, g_3)$. The tangent plane of $\mathcal{B}(g_1, g_2, g_3)$ at the point $(0, 0, \lambda)$ is the plane spanned by $\ell_0$ and $g(\lambda, \alpha, \delta)$.

We can now characterize what it means for the normal vectors $\eta(g)$ to be linearly dependent.

Lemma 2. Let $g_1, g_2, g_3, g_4 \in \mathcal{C}$ with $g_i \in \mathcal{C}(\lambda_i, \alpha_i)$, and let $\eta_i := \eta(g_i)$.

The normals $\eta_1$ and $\eta_2$ are linearly dependent if $\ell_0$, $g_1$, and $g_2$ are concurrent and coplanar. (We excluded this possibility.)

The normals $\eta_1, \eta_2,$ and $\eta_3$ are linearly dependent if and only if some two of them are, or if $\ell_0, g_1, g_2, g_3$ are concurrent or coplanar.

The normals $\eta_1, \eta_2, \eta_3,$ and $\eta_4$ are linearly dependent if and only if some three of them are, or if $g_4$ lies in the tangent plane to $\mathcal{B}(g_1, g_2, g_3)$ at $(0, 0, \lambda_4) = \ell_0 \cap g_4$.

For a family $\mathcal{F} \subset \mathcal{C}$, we define the family $\mathcal{F}^\perp := \{g^\perp(\lambda, \alpha) \mid g(\lambda, \alpha, \delta) \in \mathcal{F}\}$ of "orthogonalized" lines. We have the following result:

Lemma 3. Let $\mathcal{F} \subset \mathcal{C}$. If $\mathcal{F}^\perp$ pins $\ell_0$, then $\mathcal{F}$ pins $\ell_0$.

Proof. Assume $\mathcal{F}$ does not pin $\ell_0$, and consider the intersection $\mathcal{U} := \bigcap_{g \in \mathcal{F}} \mathcal{U}_g$. Since $\mathcal{U}$ is a semialgebraic set, there is a smooth path starting at the origin $0$ contained in $\mathcal{U}$. Let $r$ be the direction of this path in $0$. Then $r \cdot \eta(g) \geq 0$ for all $g \in \mathcal{F}$, implying $r \cdot \eta(g^\perp) \geq 0$ for all $g^\perp \in \mathcal{F}^\perp$. But then $\mathcal{F}^\perp$ does not pin $\ell_0$. 

\end{document}
The reverse of Lemma 3 is not true—it fails for lines that are not generic. The following lemma, however, shows that the reverse holds for generic families of lines, and characterizes the case where it does not hold.

**Lemma 4.** Let $\mathcal{F} \subset \mathcal{C}$ such that $\mathcal{F}$ pins $\ell_0$ but $\mathcal{F}^\perp$ does not pin $\ell_0$. Then $\mathcal{F}$ is non-generic, and $\rho := \cap_{g \in \mathcal{F}^\perp} U_g$ is a line through the origin or a half-line starting at the origin.

**Proof.** If $\rho$ has non-empty interior, then we can pick a direction $r$ from $0$ into the interior of $\rho$. The direction $r$ must make a positive dot-product with all normals $\eta(g)$, $g \in \mathcal{F}$, and so $\ell_0$ cannot be pinned by $\mathcal{F}$.

It follows that $\rho$ has empty interior. Let $S$ be the linear subspace spanned by $\rho$; it has dimension $d$ at least one (since $\mathcal{F}^\perp$ does not pin $\ell_0$) and at most three. But then $S$ must be contained in $S_{\rho^\perp}$ for at least $5 - d$ lines $g^\perp$. The normals $\eta(g^\perp)$ must be orthogonal to the $d$-dimensional subspace $S$, implying that they lie in a $(4 - d)$-dimensional subspace. But $5 - d$ vectors in a $(4 - d)$-subspace are linearly dependent, and so $\mathcal{F}$ is non-generic.

We now observe further that $S$ cannot be three-dimensional, because that would imply two linearly dependent normals, and we excluded this case.

Assume that $S$ is two-dimensional. This implies at least three linearly dependent normals. By Lemma 2, this means that there are three lines in $\mathcal{F}$ that all span the same plane with $\ell_0$. This means that these lines restrict the transversal to this plane, and the remaining lines pin it inside the plane. But this property is then also true for $\mathcal{F}^\perp$, in contradiction to our assumption that $\mathcal{F}^\perp$ does not pin $\ell_0$.

It follows that $S$ is one-dimensional. Since $\rho$ is an intersection of closed half-spaces, this means that either $\rho$ is a line through the origin or a (closed) half-line starting at the origin. \qed

Lemma 4 implies that Theorem 1 immediately generalizes to generic families.

**Theorem 5.** If the line $\ell_0$ is pinned by a generic family $\mathcal{F} \subset \mathcal{C}$ of oriented lines, then there is a subfamily $\mathcal{F}'$ of size at most five that already pins $\ell_0$.

**Proof.** By Lemma 4, $\mathcal{F}^\perp$ also pins $\ell_0$. We can now use Theorem 1 to conclude that there is a subfamily $\mathcal{F}^{\perp'} \subset \mathcal{F}^\perp$ of at most five lines that already pin $\ell_0$. By Lemma 3, the corresponding family $\mathcal{F}' \subset \mathcal{F}$ also pins $\ell_0$, proving the theorem. \qed

### 5 When first-order approximation is not enough

The only case that remains to be considered is when $\mathcal{F}$ pins $\ell_0$, but $\mathcal{F}^\perp$ does not. This really can happen, as the following example shows. The rest of this section is dedicated to showing that this example is really the only such situation.

Consider the surface $\mathcal{B}$ defined by the equation $y = xz$. Let $g_0$, $g_1$, $g_2$, $g_3$ be the lines in the intersection of $\mathcal{B}$ and the planes $z = 0, 1, 2, 3$, respectively. (That is, $g_0$ is the $x$-axis, $g_1$ is the line $(t, t, 1)$, $g_2$ is the line $(t, 2t, 2)$, and $g_3$ is the line $(t, 3t, 3)$, for $t \in \mathbb{R}$.)

We orient the four lines in alternating directions: $g_0$ and $g_2$ in the direction of increasing $x$-coordinates, $g_1$ and $g_3$ in the direction of decreasing $x$-coordinates. It is not difficult to see that any common transversal to the four lines must lie in the surface $\mathcal{B}$. This is
because in order to pass on the correct side of the four lines \( g_0, \ldots, g_3 \), a transversal not contained in \( B \) would have to intersect \( B \) at least three times (points of tangency counted twice), which is impossible as \( B \) is a quadric.

We now replace \( g_0 \) by \( g'_0 \), by rotating the line slightly around the origin inside the plane \( y = 0 \) (the tangent plane to \( B \) at the origin). For concreteness, we chose \( g'_0 \) to be the line \( z = x/100 \). This means that for points on \( g'_0 \), we have \( y - xz = 0 - x^2/100 < 0 \) for \( x \neq 0 \). This implies that \( g'_0 \) lies everywhere (except at the origin) below \( B \), which is the same as saying that lines in \( B \) pass \( g'_0 \) on the left.

It follows that \( g'_0, g_1, g_2, g_3 \) pin \( \ell_0 \). Indeed, the only transversal lying inside \( B \) is \( \ell_0 \), and the same argument as above implies that no other line can be a transversal.

If we set \( \mathcal{F} = \{g'_0, g_1, g_2, g_3\} \), then \( \mathcal{F} \) pins \( \ell_0 \), but \( \mathcal{F}^\perp = \{g_0, g_1, g_2, g_3\} \) does not.

We start with a lemma that improves the characterization of Lemma 4.

**Lemma 6.** Let \( \mathcal{F} \subset \mathfrak{C} \) be a minimal family such that \( \mathcal{F} \) pins \( \ell_0 \) but \( \mathcal{F}^\perp \) does not pin \( \ell_0 \). Then \( \rho := \bigcap_{g \in \mathcal{F}^\perp} \mathcal{U}_{g^\perp} \) is a line through the origin. In other words, there is a doubly-ruled quadric \( B \) containing \( \ell_0 \) and all lines \( g^\perp \), for \( g \in \mathcal{F} \).

We can show that in this case as well there is a constant number of lines pinning \( \ell_0 \). The proof is omitted in this abstract, and we conclude with the main theorem.

**Theorem 7.** Given a family \( \mathcal{F} \subset \mathfrak{C} \) of lines that pin \( \ell_0 \). Then there is a subfamily \( \mathcal{F}' \subset \mathcal{F} \) of at most eight lines such that \( \mathcal{F}' \) already pin \( \ell_0 \). If \( \mathcal{F} \) is generic, the size of \( \mathcal{F}' \) is five.
