

Title

Alpha-fetoprotein-producing pancreatic cancer cells possess cancer stem cell characteristics.

Abstract

We aimed to demonstrate the existence of cancer stem cells in human pancreatic cancer, and to clarify that they are alpha-fetoprotein (AFP) producing cells. Six cell lines derived from human pancreatic cancers were examined, and AsPC-1 and PANC-1 were noted to express AFP. Single cell culture assays and xenotransplantation revealed that the AFP-producing cells had the capacity for self-renewal and differentiation, and that these cells were tumorigenic. Furthermore, they were resistant to anti-cancer agents. The ABCA12 transporter was expressed in the AFP-producing cells at a level more than twice as high as that in the non-AFP-producing cells.

The AFP-producing cells were shown to be putative pancreatic cancer stem cells. Furthermore, the expression of ABCA12 appears to be associated with drug resistance.

Cancer stem cell

Pancreatic cancer

Alpha-fetoprotein (AFP)

ATP-binding cassette, sub-family A (ABC1), member 12 (ABCA12)

1. Introduction

Recent advances in stem cell biology have revealed the existence of cancer stem cells (CSCs) in various tumors, including leukemia [1], breast cancer [2], brain tumor [3] and pancreatic cancer [4, 5]. CSCs are defined as cells that possess the capacity to self-renew, to cause the heterogeneous population of cancer cells, and to initiate tumors [6]. In addition, CSCs are supposed to have long lifetime and show drug- and/or radiation-resistance, like normal tissue stem cells. These properties of the CSCs might contribute to the tumor malignancy such as rapid growth, resistance to therapy, and recurrence. Therefore, CSCs could be a new target for cancer therapies.

To investigate the characteristics of the CSCs, it is necessary to be able to successfully isolate them from the heterogeneous tumor cells. There have been several reports about the combinations of cell surface markers that can be used to isolate the CSCs from the pancreatic cancer tissues [4, 5]. However, the functions and biological relevance of the individual markers in the tumor tissues are still unknown.

Previously, we reported the existence of CSCs in cholangiocellular carcinoma, and demonstrated that these cells were as the alpha-fetoprotein (AFP) producing cells [7]. AFP is one of the major serum proteins produced by fetal hepatoblasts. In this study, we also focused on AFP as a human pancreatic cancer stem cell marker. AFP is secreted not only by the fetal liver, but also by foregut endoderm and fetal pancreas [8]. Because CSCs show several similarities to normal tissue stem cells, we hypothesized that AFP might be expressed in human pancreatic CSCs.

2. Materials and methods

2.1. Patients

Twenty-five patients with pathologically-confirmed pancreatic cancer who had undergone a pancreatic resection at Kyoto University Hospital in 2008, were included in this study. The patients included 10 males and 15 females, with a mean age at surgery of 66.7 ± 7.5 years (range, 49-77 years). Written informed consent for the use of their resected tissues was obtained from all patients in accordance with the Declaration of Helsinki. Their clinicopathological background is summarized in Supplemental Table 1.

2.2. Generation of transgenic cell lines derived from human pancreatic cancer cells

MIAPaCa-2, AsPC-1 and PANC-1 cells were obtained from the American Type Culture Collection (ATCC, Manassas, VA), SUIT-2 was from the Health Science Research Resources Bank (Osaka, Japan), and KP-1NL and QGP-1 were from the Japanese Collection of Research Bioresources cell bank (Osaka, Japan). These cells were plated on cell culture dishes (BD Biosciences, Franklin Lakes, NJ), and all six cell lines were maintained in RPMI 1640 medium (Invitrogen, Carlsbad, CA) supplemented with 10% heat-inactivated fetal calf serum (FCS; ICN Biomedicals Inc., Aurora, OH), 100 U/ml penicillin (Meiji Seika, Tokyo, Japan), and 100 μ g/ml streptomycin (Meiji Seika) at 37°C in a humidified atmosphere with 5% carbon dioxide.

The transgene plasmid vectors that expressed enhanced green fluorescent protein (EGFP) under the control of human AFP enhancer/promoter were generated as described previously [9].

The transgenic vectors were transfected using Lipofectamine 2000 (Invitrogen) according to the manufacturer's protocol. Stably transfected cells were selected in the presence of 800 $\mu\text{g/ml}$ G418 (Sigma, St Louis, MO) over a period of 30 days. The proper transgene insertion was confirmed by polymerase chain reaction (PCR). The stable transfectants were cultured in the presence of 800 $\mu\text{g/ml}$ G418.

2.3. Reverse transcription-PCR (RT-PCR)

RT-PCR was performed as described previously [9]. Primers were generated for the following human genes; EGFP, AFP, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH). Their sequences and the PCR conditions are summarized in Supplemental Table 2.

2.4. Immunocytochemistry of cultured cells

The cultured cells were fixed and stained as previously described [9, 10, 11]. An anti-human AFP rabbit antibody (DakoCytomation, Glostrup, Denmark) diluted at 1:200 was used as the primary antibody, and Alexa546-conjugated donkey anti-rabbit IgG (Molecular Probes, Eugene, OR) diluted at 1:500 was used as the secondary antibody. The stained cells were covered with Vectashield mounting medium with 4',6-diamidino-2-phenylindole (DAPI; Vector Laboratories, Burlingame, CA).

2.5. Histology and immunohistology

The harvested tumors were fixed in 3.3% formaldehyde (Wako, Osaka, Japan) for at least one week. After a thorough rinsing, the tissues were then embedded in paraffin and sectioned into 3 μm thick sections. Hematoxylin-eosin (HE) staining was performed according to a standard protocol. In order to perform immunohistological staining for AFP, the deparaffinized and rehydrated sections were incubated in 3% hydrogen peroxide in methanol for 10 minutes and then were incubated with the diluted anti-human AFP antibodies at 4°C for 16 hours. Followed by thorough rinsing, the samples were incubated for 30 minutes with horseradish peroxidase-conjugated anti-rabbit IgG (Envision+ Kit/horseradish peroxidase; DakoCytomation) and then for 1 minute with 3,3'-Diaminobenzidine (DAB) substrates (DakoCytomation). Counterstaining was performed using hematoxylin.

2.6. Flow cytometry

The cultured cells were prepared as described previously [9, 10, 11]. Dead cells were eliminated using 7-amino-actinomycin D (7-AAD; BECKMAN COULTER, Brea, CA). The cells were analyzed and isolated using a FACSVantage SE cell sorter (BD Biosciences).

For the single-cell culture analyses, individual isolated cells were inoculated into each well of 96-well culture plates using the FACSVantage SE and the CloneCyt Plus software program (BD Biosciences). That the wells contained only one cell was confirmed using a light microscope 10 to 16 hours after cell sorting. Following cell expansion after isolation of each clone, they were subjected to flow cytometry as described previously.

2.7. Cell proliferation assay and anchorage-independent growth assay

The isolated EGFP-positive and EGFP-negative cells were inoculated at a density of 1×10^3 cells per well in 96-well culture plates (BD Biosciences), and then were allowed to grow for eight days. The cell numbers were determined using the 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium, inner salt (MTS) assay (Cell Titer 96 Aqueous One Solution Reagent; Promega, Madison, WI), according to the manufacturer's protocol. After a 1 hr of incubation, the absorbance value was measured using a plate reader at 490 nm.

To examine the anchorage-independent growth of the cells, 1×10^4 EGFP-positive and EGFP-negative cells were suspended in 2.0 ml of 0.3% agar (Wako) supplemented with the culture medium. The cell suspension was layered over the bottom layer of 2.0 ml of 0.6% agar. The AsPC-1 colonies that contained more than 10 cells were counted 21 days after cell sorting, and the colonies of PANC-1 cells were counted 7 days after sorting.

2.8. Xenotransplantation

Male 8 to 12-week-old non-obese diabetic/severe combined immune deficiency (NOD/SCID) mice (CLEA Japan, Inc., Tokyo, Japan) were utilized in the transplantation experiments. The sorted cells were washed twice with PBS after flow cytometry, and resuspended in 200 μ l of a serum-free medium and Matrigel (BD Biosciences) mixture (1:1 volume). Under

general anesthesia, the cells were engrafted into the right and left dorsal areas of NOD/SCID mice subcutaneously using a 26-gauge needle. During the following 12 weeks, mice were examined periodically by visual inspection and palpation, and then they were sacrificed to extract tumors.

To investigate the composition of the tumors grown in NOD/SCID mice, serial transplantation was performed. The tumors that were generated from the single-cell-derived EGFP-positive or EGFP-negative cells were harvested. The tumor tissues were cut into small pieces by using sterile blades, and were digested with collagenase solution [12] for 60 minutes at 37°C. After rinsing twice with PBS, the cells were analyzed using a FACSCalibur (BD Biosciences), or sorted using a FACS Vantage SE. For secondary xenotransplantation, the harvested cells were cultured in G418-containing medium for at least 7 days to eliminate cells originated from the host mice. Thereafter, these cells were sorted according to the EGFP fluorescence, and then 5×10^4 cells of the EGFP-positive or EGFP-negative fractions were transplanted into NOD/SCID mice.

All experimental procedures utilizing animals were performed in accordance with the Animal Protection Guidelines of Kyoto University.

2.9. Drug resistance assay

To investigate the resistance of the cells to anticancer agents; 5-fluorouracil (5-FU; WAKO) and gemcitabine (GEM; WAKO) were added to the cultures of the EGFP-positive and EGFP-negative cells for 4 days in the presence of the anticancer agents at various concentrations

(from 1×10^{-12} M to 1×10^{-4} M). To determine the half-maximal effective concentration (EC_{50}) of these agents, MTS assays were performed after the 4 day-culture in the presence of these anticancer agents at various concentrations. The proportions of the EGFP-positive cells were analyzed with a FACSCalibur.

2.10. Quantitative PCR (qPCR)

The total RNA was extracted from the freshly sorted EGFP-positive and EGFP-negative cells of the AsPC-1 or PANC-1 cell lines, using an RNeasy Mini Kit (Qiagen, Chatsworth, CA) and treated with RNase-free DNase (Qiagen). The total RNA (0.5 μ g) was reverse-transcribed into cDNA using the RT2 First Strand Kit (SABiosciences, Frederick, MD) according to the manufacture's protocol. The qPCR assays were performed on an ABI 7500 (Applied Biosystems, Foster City, CA) using the Human Drug Transporters RT2 Profiler PCR Array and RT² SYBR Green Master Mix (SABiosciences) according to the manufacture's protocol. The differences in mRNA expression between the EGFP-positive and EGFP-negative cells was calculated based on the DDCT method. Results were obtained from three independent trials.

2.11. Statistical analysis

All experiments were performed at least three times. The results are given as the means \pm SD. The statistical analyses were performed using Student's t-test, Dunnett's multiple comparisons and

repeated-measures analyses of variances (ANOVA). $P < 0.05$ was considered to be statistically significant. All statistical tests were two-sided.

3. Results

3.1. Generation of transgenic pancreatic cancer cell lines

RT-PCR revealed that AFP expression was observed in both the AsPC-1 and PANC-1 cell lines (Fig. 1A). The AFP-EGFP reporter vector was transfected into the six human pancreatic cancer cell lines. Only the AsPC-1 and PANC-1 cells exhibited EGFP fluorescence with fluorescent microscopy (Fig. 1B, C); the other four cell lines did not, despite the fact that they possessed the transgene in their genomic DNA (data not shown). The AsPC-1 cell line is derived from the ascites of a pancreatic adenocarcinoma patient [13], and the PANC-1 line is from a pancreatic carcinoma of ductal origin [14]. A flow cytometric analysis showed that $25.1 \pm 1.1\%$ (n=3) of the AsPC-1 cells and $6.5 \pm 1.1\%$ (n=3) of the PANC-1 cells expressed the EGFP fluorescence (Fig. 1D, E). The sorted EGFP-positive cells expressed both EGFP and AFP mRNA, whereas the sorted EGFP-negative cells did not express either molecule (Fig. 1F), thus indicating that the EGFP-positive cells correspond to the AFP-producing cells, and that cell sorting could be used to divide these cells according to their EGFP expression. Therefore, a further investigation of the AFP-producing cells in the both cell lines was conducted to determine whether or not they were pancreatic CSCs.

3.2. Single cell sorting and culture assay

Since these cell lines were heterogeneous populations, single-cell culture assays were performed in order to examine their self-renewal and differentiation capabilities. A single cell was

sorted and cultured in a well of a 96-well culture plate. Following cell expansion by four passages, flow cytometric analyses were performed. A single EGFP-positive cell generated both EGFP-positive and EGFP-negative cell fractions (Figs. 2A, B, E, F). One EGFP-negative cell, however, produced only the EGFP-negative fraction (Figs. 2C, D, G, H). These flow cytometric findings were reproducible in three trials (four EGFP-positive clones and five EGFP-negative clones were obtained from AsPC-1, and twelve EGFP-positive and twelve EGFP-negative clones from PANC-1), and the transgene was identified in the genomic DNA of all these clones (Supplemental Figure 1). These results indicated that the EGFP-positive cells had the ability to self-renew and the ability to generate the EGFP-negative cell fraction. These results also suggested that the AFP-producing cells of both cell lines had progenitor-like characteristics.

3.3. *In vitro* cell proliferation assay

To compare the *in vitro* tumorigenicity between the EGFP-positive and EGFP-negative cells, cell proliferation and the anchorage-independent cell growth assays were performed. In both cell lines, the EGFP-positive cells exhibited significantly higher proliferation than did the EGFP-negative cells ($P < 0.05$, $n = 3$; Fig. 3A, B). Moreover, the EGFP-positive cells showed stronger colony-forming abilities (approximately 2.5-fold in AsPC-1 and 4-fold in PANC-1) in soft agar than the EGFP-negative cells did ($*P < 0.005$, $**P < 0.001$, $n = 3$; Fig. 3C, D). These findings suggest that the EGFP-positive cells have stronger tumorigenic and malignant potentials *in vitro* than do the EGFP-negative cells.

3.4. Xenotransplantation into immunodeficient mice

To examine the tumorigenicity *in vivo*, the EGFP-positive or EGFP-negative cells were transplanted subcutaneously into the backs of NOD/SCID mice. A total of 10,000 to 500 cells and the mice were observed for 12 weeks. Both the EGFP-positive and EGFP-negative cells formed tumors in NOD/SCID mice. There were no differences in the proportion of tumor formation, or the time until tumor detection between the EGFP-positive and EGFP-negative cells in the both cell lines (Supplemental Table 3).

To further examine the characteristics of the cellular differentiation potential *in vivo*, serial transplantation was performed. The EGFP-positive clones derived from the single-cell cultures were used as donor cells (Fig. 4A, G). The EGFP-positive and EGFP-negative fractions were isolated before the primary transplantation (Fig. 4B, H). In both cell lines, the tumors derived from the xenotransplantation of the EGFP-positive cells had both EGFP-positive and EGFP-negative cell fractions (Fig. 4D, J). In contrast, the tumors from the EGFP-negative cells generated only the EGFP-negative fraction (Fig. 4C, I). These results demonstrated the self-renewal and differentiation abilities of the EGFP-positive cells *in vivo*. Furthermore, the EGFP-positive and EGFP-negative cells isolated from the EGFP-positive cell-derived tumors were transplanted again at 5×10^4 cells into NOD/SCID mice. Both cell lines formed tumors. The tumors from the EGFP-positive cells had both the EGFP-positive and EGFP-negative cell fractions (Fig. 4F, L), and the tumors from the EGFP-negative cells had only EGFP-negative fraction (Fig. 4E, K). These

results indicated that the EGFP-positive cells kept their self-renewal potential and ability to differentiate through several passages *in vivo*.

3.5. Drug resistance assay

The resistance of the two cell lines to 5-FU and GEM was examined. EC_{50} values were calculated based on MTS assays, showing that the EC_{50} values for 5-FU were 5.15×10^{-6} M for AsPC-1 and 1.03×10^{-6} M for PANC-1, respectively. Those for GEM were 5.48×10^{-10} M for AsPC-1 and 4.54×10^{-8} M for PANC-1. In both cell lines, the proportions of the EGFP-positive cells increased when the whole cell populations were cultured in the presence of these anticancer agents around the EC_{50} (Fig. 5A-D). The number of total living cells was decreased at concentrations over the EC_{50} . It was demonstrated that the EGFP-positive cells in both cell lines had greater drug resistance against both 5-FU and GEM.

In order to examine the mechanism responsible for the drug resistance, the expression levels of mRNA related to drug transporters that move cytotoxic substances outside the cell membrane were compared between the AFP-producing cells and the non-AFP-producing cells by qPCR assays. The ABCB1 transporter in AsPC-1 cells, and the ABCB4 transporter in PANC-1 cells, which are known multidrug resistance transporters, were expressed in the EGFP-positive cells at more than twice the levels as that in the EGFP-negative cells. In both cell lines, the ABCA12 transporter was highly expressed in the EGFP-positive cells (Fig. 5E-H).

3.6. Histology and immunohistology of surgical specimens

In order to examine the AFP expression in human clinical pancreatic cancer, immunohistological assays were performed utilizing 25 surgical samples. A small number of tumor cells (less than 5%) expressed AFP in 16 of the 25 patients with pancreatic cancer (Figure 6, A-C). However there were no AFP expressing cells in any of the examined sections of the other 9 patients (Figure 6D). The preoperative serum AFP values were below the normal range in patients who were examined. The patients' clinical background and tumor pathological features did not correlate with the AFP expression (Supplemental Table 1).

4. Discussion

CSCs are thought to have many similarities to normal tissue stem cells, and are defined by their ability to self-renew, to generate heterogeneous lineages of cancer cells, and to initiate tumor growth [6]. Although many previous reports concerning the identification of CSCs used combinations of cell surface markers, we focused on AFP as a marker for pancreatic CSCs. AFP is produced by the foregut endoderm and its derivatives; the fetal liver and pancreas during the embryonic period [8]. Therefore, we hypothesized that pancreatic CSCs might express AFP if the CSCs existed in the pancreatic cancer tissues.

In this study, we transfected a plasmid vector that expressed EGFP under the control of the AFP enhancer/promoter into the six human pancreatic cancer cell lines, in order to isolate and characterize the AFP-producing cells. AFP-producing cells were found in two of the six cell lines (AsPC-1 and PANC-1). The AFP-producing cells in both cell lines were demonstrated to have the capacity for self-renewal and differentiation to generate a non-AFP-producing cell fraction *in vitro* and *in vivo*, whereas the non-AFP-producing cells did not possess these characteristics. The AFP-producing cells were also shown to have a higher proliferation activity *in vitro* and tumorigenicity *in vivo*. These results indicated that the AFP-producing cells corresponded to cancer progenitor cells in pancreatic cancer. The non-AFP-producing cells had the same tumorigenicity as the AFP-producing cells *in vivo*. This was probably because the tumor cell lines had, in general, a higher malignant potential than their original tumor tissues [15]. However, the non-AFP-producing cells did not generate heterogeneity concerning EGFP expression in the

xenografted tumor tissues.

The existence of the AFP-producing cells in human clinical specimens was also demonstrated by the immunohistological analyses. A small number of tumor cells expressed AFP in 16 of the 25 patients with pancreatic cancer. There have also been several reports of pancreatic cancers with high serum AFP levels, which tend to be associated with a worse prognosis because of high rates of liver metastasis [16]. These findings suggested that AFP could be a CSC marker in clinical cases. Although there were no patients with high preoperative serum AFP values in our 25 cases, the AFP-producing pancreatic cancers might represent cases of abnormal proliferation or increased numbers of AFP-producing CSCs, which would result in a poorer prognosis.

The CD24⁺CD44⁺epithelial specific antigen (ESA)⁺ [4], CD133⁺, and CD133⁺CXCR4⁺ cells in pancreatic cancer tissues [5] have previously been reported as pancreatic CSCs. We examined the relationship between the AFP expression and these reported cell surface markers. In the PANC-1 cells, the CD24-positive or CD133-positive cell fractions included a large part of the EGFP-positive cells. The AFP-producing PANC-1 cells were enriched in the CD24⁺CD133⁺ cell fraction, confirming that CD24 and CD133 are useful for isolating CSCs in some pancreatic cancers. On the other hand, the AsPC-1 cells had neither CD24-positive nor CD133-positive cell fractions. In addition, the expression of CD44, ESA, and CXCR4 did not correlate with the AFP expression in either cell line (Supplemental Figure 2). These findings suggested that there might be several types of CSCs in various stages of differentiation, and that the profiles of cell surface markers could vary among these CSCs. The CD133⁺CXCR4⁺ cells were found in the tumor

invasive front [5], suggesting that CSCs might change their phenotype depending on their environment.

AFP-producing cells were not found in all cell lines or all surgical specimens. These findings raise the question whether all pancreatic cancer tissues have their own CSCs. Furthermore, it remains unclear whether all pancreatic CSCs have a common marker, or whether, as mentioned above, different markers and phenotypes may occur depending on the microenvironment. Further studies are necessary to answer these questions. However, it would be biologically difficult to find a common marker for pancreatic CSCs because of the genetic instability of CSCs [17].

CSCs are also assumed to contribute to chemoresistance and radioresistance. This study demonstrated that the AFP-producing cells in both cell lines showed resistance to 5-FU and GEM compared to non-AFP-producing cells. The qPCR analyses revealed that the ABCA12 gene, which encodes one of the ABC transporter family proteins, was highly expressed in the AFP-producing cells of both cell lines. The expression of ABCA12 has been reported to be predominantly found in the skin and the stomach. This transporter is assumed to play a role in skin lipid homeostasis, and is highly expressed in healthy keratinocytes. Mutations in the ABCA12 gene were detected in patients suffering from lamellar ichthyosis type 2 and harlequin ichthyosis, a rare hereditary disease characterized by skin desquamation over the whole body [18]. However, there have been only a few reports about ABCA12 expression in cancer. In these reports, positive correlations were found between the expression of ABCA12 and the resistance of breast cancer to neoadjuvant chemotherapy [19], and a retinoblastoma cell line was reported to highly express the ABCA12

gene [20]. Our results suggested that the ABCA12 transporter may be associated with the chemoresistance of pancreatic CSCs. It has also been postulated that some CSCs are able to enter into the G0 phase of the cell cycle, and this characteristic is also thought to enhance their chemoresistance. However, the cell cycle analyses of our cell lines showed no significant differences in the proportions of G0 phase cells between the AFP-producing and non-AFP-producing cells (data not shown).

In conclusion, the AFP-producing cells were shown to be cancer progenitor cells, or putative CSCs of human pancreatic cancer. In addition, the drug transporter ABCA12 was preferentially expressed in the AFP-producing cells, suggesting that the high expression of ABCA12 may be associated with the CSCs' resistance to anti-cancer agents. AFP and ABCA12 may represent a new prognostic marker or target for cancer therapies.

Legends

Figure 1.

The human pancreatic cancer cell lines that expressed EGFP under the control of the human AFP enhancer/promoter. (A) An RT-PCR analysis of the six pancreatic cancer cell lines. (B, C) The stable transfectants of AsPC-1 and PANC-1 cells expressed EGFP fluorescence in fluorescent microscopy images (right panels). The left panels show the phase contrast images of the same visual fields of the right panels. Original magnification: 200 \times . (D, E) A flow cytometric analysis revealed the AsPC-1 and PANC-1 cells express EGFP in $25.1 \pm 1.1\%$ and $6.5 \pm 1.1\%$ of cells, respectively. The vertical axis indicates the 7-AAD fluorescence and the horizontal axis indicates the intensity of EGFP. (F) In both cell lines, the sorted EGFP-positive cells expressed mRNA for both EGFP and AFP (left lane), whereas the sorted EGFP-negative cells expressed neither EGFP nor AFP mRNA (right lane). GAPDH was used as an internal control and samples without reverse transcriptase ($-RT$) served as a negative control.

Figure 2.

Single cell sorting analyses of the AFP-producing EGFP-positive cells and non-AFP-producing EGFP-negative cells. (A, E) The individual EGFP-positive cells were sorted into each well of 96 well culture plates. The single cell indicated by the circle generated both the EGFP-positive and EGFP-negative cell fractions (B, F). On the other hand, the single EGFP-negative cell (C, G) produced only the EGFP-negative cell fraction (D, H).

Figure 3.

Comparison of tumorigenicity *in vitro* between the AFP-producing EGFP-positive and non-AFP-producing EGFP-negative cells. (A, B) A comparison of the MTS assays between the two cell populations was made using repeated-measures ANOVA (both $P < 0.05$). (C, D) The graph indicates the colony numbers of the EGFP-positive and EGFP-negative cells growing in soft agar (Student's *t*-test; * $P < 0.005$, ** $P < 0.001$). The results are presented as the means \pm SD.

Figure 4.

Flow cytometry of the serially transplanted AsPC-1 (A-F) and PANC-1 (G-L) tumors. The cultured AsPC-1 (A, B) and PANC-1 (G, H) cells derived from single cells were isolated according to their EGFP fluorescence, and transplanted into NOD/SCID mice. The tumors derived from the EGFP-positive (D and J) and EGFP-negative cells (C and I) were enzymatically digested and analyzed by flow cytometry. The EGFP-positive and EGFP-negative cells were isolated from the EGFP-positive cell-derived tumor (D and J), and were secondarily transplanted to the NOD/SCID mice. The EGFP-negative cell-derived secondary tumor had only EGFP-negative cells (E and K) but the EGFP-positive cell-derived tumor had both EGFP-positive and EGFP-negative components (F and L).

Figure 5.

The drug resistance analyses for 5-FU (A, B) and GEM (C, D). The vertical axis indicates

the proportion of the EGFP-positive cells, and the horizontal axis indicates the concentration of the agent. In both cell lines, the number of EGFP-positive cells still increased when exposed to these drugs over the usual EC₅₀. **P* < 0.05 compared with the control in Dunnett's multiple comparisons. Quantitative PCR (qPCR) arrays for drug transporters were performed (E, G). Genes that showed mRNA expression more than twice or less than half in the AFP-producing EGFP-positive cells compared to the non-AFP-producing EGFP-negative cells are shown in (F, H). In both cell lines, the mRNA for ABCA12 was highly expressed in the EGFP-positive cells.

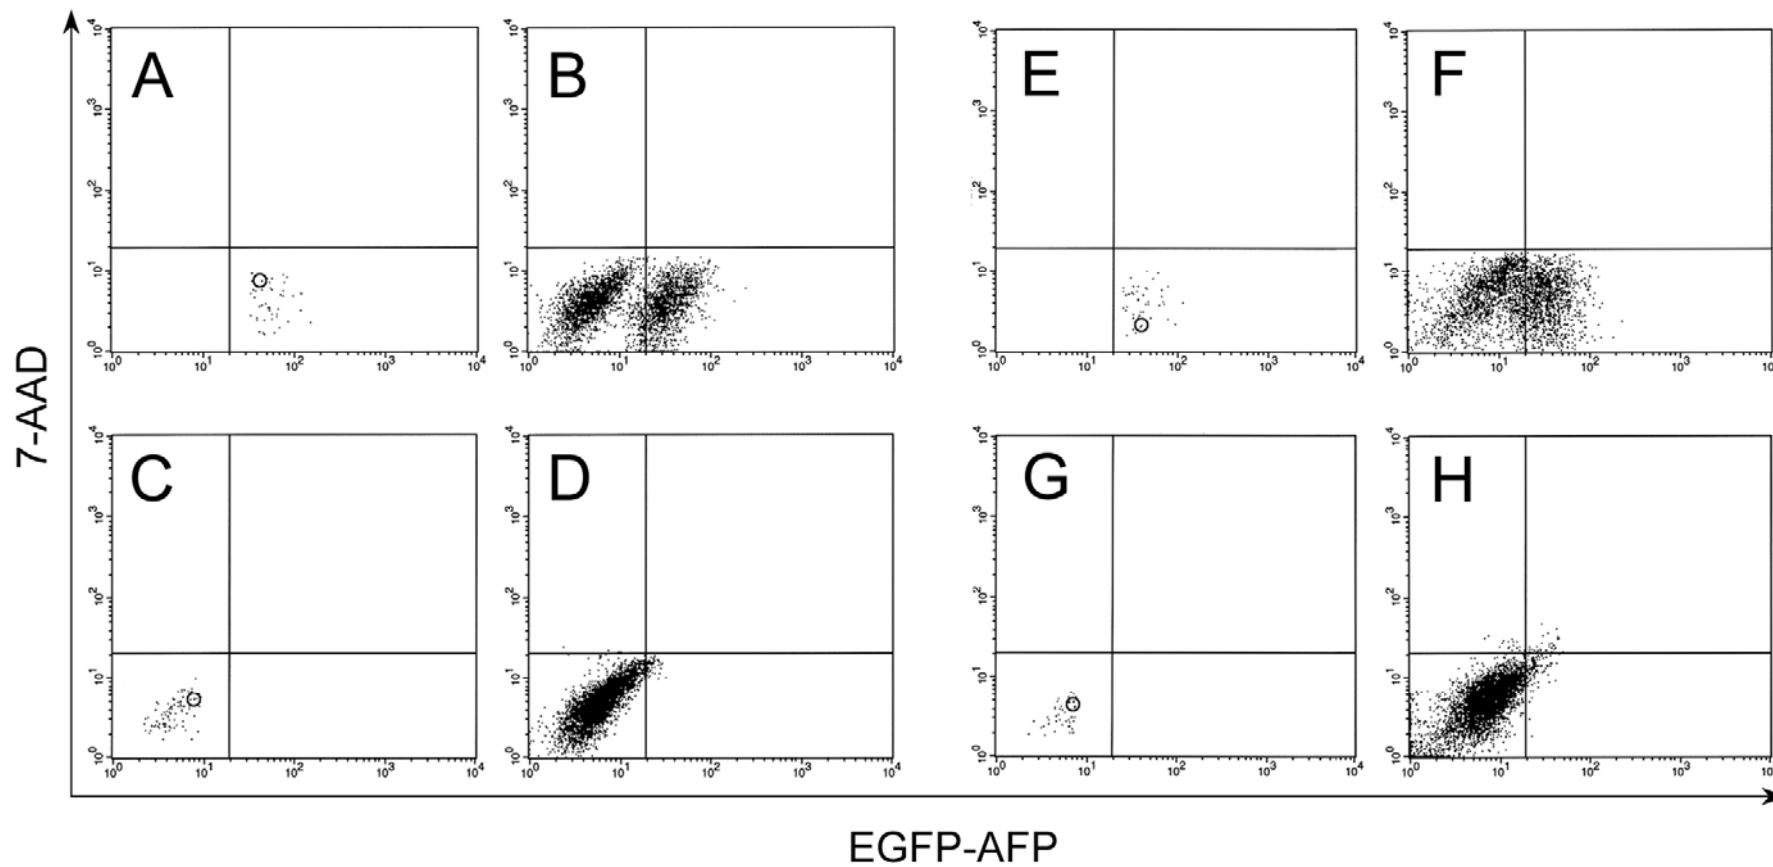

Figure 6.

The immunohistological analyses of human pancreatic cancer tissues. Figures A-C were obtained from samples from three different patients with AFP-expressing tumor cells, and figure D was from one patient without AFP-expressing cells. The left row indicates the HE staining of tumor tissue; the center and right rows show immunostaining for AFP. The arrowheads indicate the cells that express AFP. Original magnifications: the left two rows, 100×; the right row, 400×.

Supplemental Figure 1

Genomic PCR of clones generated from single cell cultures. The genomic DNA was extracted using DNazol Reagent (Invitrogen) according to the manufacturer's protocol. All the AsPC-1 and PANC-1 clones generated from single cell cultures were demonstrated to have a part of the transfected genes; EGFP. The primer sequences and PCR conditions are listed in Supplemental Table 2.

Supplemental Figure2

Flow cytometric analyses to show the relationship between EGFP-AFP and other stem cell surface markers in AsPC-1 (A) and PANC-1 (B). These cells were analyzed and isolated using a FACSVantage SE cell sorter. The phycoerythrin-conjugated (PE) antibodies were; anti-CD24, anti-CD34, anti-CD44, anti-CD45, anti-CD49f, anti-CD90, anti-CD117, anti-CD133 (MiltenyiBiotec, BergischGladbach, Germany), anti- epithelial cell adhesion molecule (EpCAM, same as epithelial specific antigen, ESA; Abcam, Cambridge, UK), and anti- CXC chemokine receptor 4 (CXCR4; R&D systems, Minneapolis, MN). Unless noted, antibodies were purchased from BD Biosciences. The vertical axis indicates the expression of the individual markers and the horizontal axis represents the intensity of EGFP. In PANC-1, the expression of EGFP was observed to positively correlate with CD24 and CD133.

AFP immunocytochemistry of non-transgenic PANC-1 cells sorted according to the expression of CD24 and CD133(C-F). The CD24+ CD133+ fraction was enriched with the AFP-positive cells (D).

GAPDH; glyceraldehyde-3-phosphate dehydrogenase

Supplemental Table 3

		1×10^4	5×10^3	5×10^2
AsPC-1	EGFP +	5/6	3/3	1/3
	EGFP -	5/6	3/3	0/3
PANC-1	EGFP +	4/5	8/9	3/6
	EGFP -	4/6	7/9	3/6

The table shows the tumor incidence of the cell transplanted mice. The top row indicates the cell numbers of transplantation per mouse. The numerators indicate the number of mice that had tumors, and the denominators indicate the number of mice that received cell transplantations. The tumorigenicity between the EGFP-positive and the EGFP-negative cell transplanted group was analyzed using Fisher's exact test. Although $P < 0.05$ was considered to be statistically significant, no significant difference was observed in the tumorigenicity between the AFP-producing
