(Received 5 December 2009; accepted 22 March 2010; published online 26 April 2010)

Following 157 nm photoexcitation of amorphous solid water and polycrystalline water ice, photodesorbed water molecules (H2O and D2O), in the ground vibrational state, have been observed using resonance-enhanced multiphoton ionization detection methods. Time-of-flight and rotationally resolved spectra of the photodesorbed water molecules were measured, and the kinetic and internal energy distributions were obtained. The measured energy distributions are in good accord with those predicted by classical molecular dynamics calculations for the kick-out mechanism of a water molecule from the ice surface by a hot hydrogen (deuterium) atom formed by photodissociation of a neighboring water molecule. Desorption of D2O following 193 nm photoirradiation of a D2O/H2S mixed ice was also investigated to provide further direct evidence for the operation of a kick-out mechanism. © 2010 American Institute of Physics. [doi:10.1063/1.3386577]

I. INTRODUCTION

In interstellar molecular clouds characterized by dense clumps of material and excess vacuum-ultraviolet (vuv) photons, photoirradiation on dust grains induces desorption of molecules. Photodesorption is often invoked to account for the high gas-phase abundances of less volatile molecules, such as water, that are observed under conditions where complete freeze-out onto dust grains might otherwise be expected.1,2 Given the typical size of dust grain and magnitude of vuv flux inside dense molecular clouds, the arrival rate of vuv photons on a dust grain is estimated to be about one photon per day.3,4 A proper appreciation of the effects of single UV absorption events is thus likely to be important in developing a realistic picture of photodesorption in dense molecular clouds. Several experimental studies of the photodesorption of water molecules from ice surfaces have been performed.5–9 Wolf et al. studied water molecule desorption following 193 nm (2–40 mJ cm−2) irradiation of the water bilayer adsorbed on a Pd(111) surface, which is due to metal substrate excitations, and reported that the photodesorption became inefficient when water multilayers (>4 ML) were adsorbed.10 Öberg et al.11 used a vuv lamp emitting in the range of 7.0–10.5 eV (1.1–5.0 × 1013 photons cm−2 s−1) to irradiate ices at surface temperatures of 18–100 K and detected H2O, OH, H2, and O2 as desorbing species. Molecular dynamics (MD) calculations by Andersson and van Dishoeck3 proposed a kick-out mechanism for water photodesorption following absorption of a single UV photon, i.e., an H2O molecule is ejected from the ice by momentum transfer, mainly to the oxygen atom in H2O, from an energetic H atom released by photodissociation of a neighboring H2O, i.e., reactions (1) and (2).

\[
\Delta H \, (kJ \, mol^{-1}) , \quad H_2O(ads \, or \, bulk) \rightarrow \text{hot H} + \text{OH} \, , \, 541.6 , \quad (1) \\
\text{hot H} + H_2O(ads) \rightarrow \text{H} + H_2O \, . \, , \, 44.5 , \quad (2)
\]

In the case of 157 nm (\(E_{\text{phot}} = 762.0 \, kJ \, mol^{-1}\)) photolysis, the excess energy over and above that required for reaction (1), \(E_{\text{avail}}(1)\), is 220.4 kJ mol−1. Thermodynamic values are calculated using solid or dilute solution phase thermodynamic data for the condensed or adsorbed water (“ads”) and gas-phase data for other species.12,13 We have previously investigated the photodesorption processes of energetic hydrogen atoms and water molecules from both amorphous solid water (ASW) and polycrystalline water ice (PCI) at 90 K using pulsed 157 or 193 nm laser radiation, i.e., at wavelengths within the first absorption band of the ice, thereby revealing the translational and internal energy distributions of the photodesorbed species.14–16

In the present work, we have performed (a) an experimental study of photodesorption mechanisms and dynamics of water molecules from ASW and PCI at 90 K seeking evidence for the operation of the kick-out mechanism, i.e., reaction (2), and (b) classical MD calculations of the translational and rotational energies of photodesorbed H2O molecules from an ASW ice surface.

II. EXPERIMENTAL

A. Apparatus and preparation of ice

The apparatus has been described before,\(^1\) and only details relevant to the present experiments are given here. A vacuum chamber was evacuated to a base pressure of \(10^{-8}\) Torr using two turbo-molecular pumps in tandem (Shimadzu, 800 and 50 l s\(^{-1}\)). An optically flat sapphire disk substrate, sputter coated with a thin polycrystalline film of Au(111), was supported in the center of the chamber by a liquid-nitrogen-cooled manipulator connected to an X-Y-Z stage.\(^1\) The temperature of the substrate was controlled to within 1 K.

Three types of ice samples were prepared: amorphous solid \(\text{H}_2\text{O}\) and \(\text{D}_2\text{O}\) water ices [henceforth termed ASW(\(\text{H}_2\text{O}\)) and ASW(\(\text{D}_2\text{O}\)), respectively], polycrystalline \(\text{H}_2\text{S}\) water ice (PCI(\(\text{H}_2\text{O}\))), and a \(\text{D}_2\text{O}\) ice sample containing an \(\text{H}_2\text{S}\) ice interlayer. ASW were prepared by backfilling deposition of water vapor onto the polycrystalline gold substrate.\(^1\) The prepared ice was exposed to a mixture of \(\text{H}_2\text{S}\) for 60 min and then further maintaining the ice at 130 K for 30 min for annealing purposes. The prepared PCI for 30 min for annealing purposes. The prepared PCI(\(\text{H}_2\text{O}\)) may have both cubic and hexagonal structures. Its surface is partially disordered due to grain boundaries.\(^1\) Since time-of-flight (TOF) spectra of the photofragment hydrogen atoms following 193 nm photolysis of water molecules on ice surface strongly depend on surface morphology,\(^1\) the morphology of the prepared PCI surface was confirmed by observing the TOF spectrum of the photofragment hydrogen atoms. Details of the characteristics of prepared ASW and PCI have been discussed in our previous publications.\(^1\)

To obtain the nascent internal and kinetic energy distributions of photodesorbed water molecules without the influence of the ice/gold interface, we performed thick-ice experiments. The water vapor exposure was typically 1500 L (1 L = 1 \(\times\) 10\(^{-10}\) Torr). This exposure resulted in formation of roughly 500 ML of \(\text{H}_2\text{O}\) on the substrate if we adopt the reported experimental conversion factor of 1 ML deposition by 3 L exposure,\(^2\) which are expected to be sufficient thick to negate the possible influence of reactions at the ice/gold substrate interface and of any photoelectrons from the gold substrate.\(^1\)

For the \(\text{D}_2\text{O}:\text{H}_2\text{S}\) mixed ice sample, the ASW(\(\text{D}_2\text{O}\)) was exposed to a mixture of \(\text{H}_2\text{S}(30\%) + \text{N}_2(70\%)\) gas. The \(\text{H}_2\text{S}\) exposure was \(\sim 80\) L for 10 min duration at 90 K. After \(\text{H}_2\text{S}\) deposition, \(\text{D}_2\text{O}(10-70\) L) was further deposited on the \(\text{H}_2\text{S}\) layer.

Unfocused \(\text{F}_2\) excimer laser (Lambda Physik, OPTexPro, Göttingen, Germany) radiation at 157 nm with a pulse duration of 10 ns was incident on the ice surface at an angle of \(\sim 80\)° to the surface normal and at a fluence, \(F < 0.1\) mJ cm\(^{-2}\)(\(\sim 10^{14}\) photons cm\(^{-2}\) pulse\(^{-1}\)); the corresponding fluence when using an ArF excimer laser (Lambda Physik, COMPex) at 193 nm was \(F < 1.0\) mJ cm\(^{-2}\)(\(\sim 10^{15}\) photons cm\(^{-2}\) pulse\(^{-1}\)). Although Yabushita \etal\ previously observed hydrogen atom photofragments following 193 nm photodissociation of ASW and PCI,\(^1\) 193 nm irradiation of ASW(\(\text{H}_2\text{O}\) or \(\text{D}_2\text{O}\)) resulted in no measurable \(\text{H}_2\text{O}\) or \(\text{D}_2\text{O}\) resonance-enhanced multiphoton ionization (REMPI) signal in such thick condensed ice and weak 193 nm laser intensity, which is consistent with the previously reported experimental study by Wolf \etal.\(^1\)

The photolirradiated area in all cases was a disk of radius 6 mm. As shown in Fig. 1(a), photodesorbed \(\text{H}_2\text{O}\) and \(\text{D}_2\text{O}\) molecules were detected by 2+1 REMPI via the \(C(000)\) \(-X(000)\) transition, at wavelengths in the range of 247.5–248.5 nm produced by frequency doubling the output of a Nd\(^{3+}\):YAG pumped dye laser (Lambda Physik, SCANmate) and collected with a small mass spectrometer aligned perpendicularly to the ice surface.

B. Simulation of 2+1 REMPI spectra of water molecules

PGOPHER, a program for simulating the rotational structure accompanying one- and multiphoton electronic transitions,\(^2\) was used to simulate the measured 2+1 REMPI spectra and thereby establish best-fit values of the rotational temperatures of the water products. Spectroscopic parameters for the ground and excited state levels of \(\text{H}_2\text{O}\) and \(\text{D}_2\text{O}\) were taken from the literature,\(^1\) including a recent re-examination of the two photon spectra. The simulation included the effect of excited state predissociation, as discussed in the cited works, which gives a predissociation rate that scales broadly with \(K_s\), i.e., with the expectation value of square of the rotational angular momentum about the \(a\)-axis in the \(C\) state level of interest. The simulations only included the origin band of the \(C-X\) transition and gave a reasonably good fit to the spectra.

![Diagram](image_url)
Relatively little information is available on vibrationally excited states of the C state, but given the similarity of the Rydberg and ground states of water, we would expect any vibrationally excited states to give the strongest spectra in the same region as the origin band. The good fit to ground state only spectra suggests little vibrational excitation in the H2O and D2O products, though we note that Uselman et al. suggested an increasing degree of predissociation for higher C state vibrational states, which would make the states harder to detect for increasing vibrational energy, and our detection method is probably completely insensitive to molecules with a large degree of vibrational or rotational excitation.

The spin temperature was taken to be the same as the rotational temperature for both H2O and D2O. There is some discussion (see, for example, Bonev et al.) on the question of whether spin temperatures in comets are always in equilibrium, though note that for all the temperatures used here (>50 K), the ortho:par ratios are essentially the statistical values of 3:1 for H2O and 2:1 for D2O. A lower temperature experiment would be necessary to probe any nuclear spin state selectivity.

C. Simulation of TOF spectra of desorbed water molecule

TOF spectra of photoproducts were taken as a function of time, \( t \), between the photolysis and REMPI laser pulses using a delay generator (Stanford Research) in order to investigate the translational energies of the desorbing photoproducts as shown schematically in Fig. 1(a). The measured TOF spectra, \( S(t, T_{\text{trans}}) \), were fitted to a Maxwell–Boltzmann (MB) distribution, \( S_{\text{MB}} \), defined by a translational temperature, \( T_{\text{trans}} \). Details regarding the simulation of such TOF spectra in terms of Eq. (3) have been reported previously.

\[
S_{\text{MB}}(t, T_{\text{trans}}) = r^3 \cdot \exp\left[-\frac{m r^2}{2 k_B T_{\text{trans}}^2}\right],
\]

where \( r \) is the flight distance to the REMPI probe region given by \( r = (L^2 + R^2)^{1/2} \) as shown in Fig. 1(a). In these calculations we assume that signals come from a disk (uv photoirradiation area) with a radius of 6 mm, and the detection probability is proportional to \( 2\pi R d R / (L^2 + R^2) \), where \( L=2 \) mm is a vertical flight distance and \( R(0 \leq R \leq 6 \text{ mm}) \) is the radius of the irradiation area. The MB distribution, \( P_{\text{MB}}(E_r) \), as a function of translational energy, \( E_r \), is characterized by the averaged translational energy, \( \langle E_r \rangle = 2 k_B T_{\text{trans}} \), where \( k_B \) is the Boltzmann constant.

\[
P_{\text{MB}}(E_r) = (k_B T_{\text{trans}})^2 \cdot E_r \cdot \exp(-E_r/k_B T_{\text{trans}}).\]

Conversion from the \( E_r \) distribution to the TOF distribution was performed using the Jacobian given by Zimmerman and Ho. The angular distribution of the molecules photodesorbed from the ice surface was assumed to follow a \( \cos^n \theta \) function, where \( \theta \) is the surface polar coordinate. \( n = 0 \) was adopted in the best-fitting procedures.

D. MD calculation method

All our calculations have been performed using classical MD methods with analytical potentials. Details of the computational procedure have been described in the work of Andersson et al. Here, only a brief outline of the methods will be presented.

1. Amorphous water ice

To create an amorphous ice slab, the procedure outlined in the work of Al-Halabi et al. was used. In brief, a slab of eight bilayers (16 monolayers) of crystalline ice was first created consisting of a cell containing 480 molecules. After the transition to amorphous ice, the resulting amorphous ice structure most closely resembles the structure of compact amorphous ice obtained experimentally and is thought to be representative of the structure of interstellar water ice.

2. Initial conditions

Once the ice surface is set up, one H2O molecule is chosen to be photodissociated. This molecule is then made completely flexible, and its intramolecular (internal) interactions are governed by an analytic potential energy surface for the first electronically excited state (the \( \Lambda ^1 \text{B}_2 \) state) of gas-phase H2O based on high-quality \textit{ab initio} electronic structure calculations. This excited potential is fully repulsive so that absorption into this state leads to dissociation of the H2O molecule into H+OH. Dissociation of molecules in the top three monolayers has been considered. For each monolayer all 30 molecules have been dissociated, one molecule at a time. For each molecule 10,000 configurations and momenta were sampled from a Wigner distribution of the vibrational ground state of H2O. To reproduce the experimental conditions most closely, only those configurations that correspond to excitation energies in the range of 7.8–8.0 eV (155–159 nm) were chosen as initial conditions for the trajectories. Out of the initial 900,000 configurations, about 70,000 were in this range and were used for the dynamics calculations.

3. Dynamics of the dissociating molecule

After putting the molecule in the excited state, the dissociating trajectory is integrated with a time step of 0.02 fs. A maximum time of 20 ps has been used before terminating the trajectory. Most of the trajectories (99.5%) were terminated before that because the system was found in one of the final outcomes with negligible probability of transforming into a different state. When the excited H2O dissociates, the intermolecular interactions are smoothly switched into separate interactions between the photoproducts and water ice, i.e., H–H2O and OH–H2O potentials. All details of the potentials and the functions used to switch between different potentials are given in Andersson et al. The switching functions connect the partial charges, the dispersion interactions and repulsive potentials between the H2O–H2O potentials and the OH–H2O and H–H2O potentials affecting the dissociating molecule.
III. EXPERIMENTAL RESULTS

A. Photodesorption of H₂O following 157 nm photoirradiation of ASW(H₂O)

Figure 2(a) shows a rotationally resolved REMPI spectrum of H₂O(v=0) molecules observed following 157 nm photoirradiation of ASW(H₂O) at 90 K and a fixed delay time, t=2.5 μs. The best-fit simulation obtained using the appropriate two-photon rotational line strengths and widths given the previously reported rotational level dependent predissociation of the C(v=0) state is shown in Fig. 2(c). By comparison with spectral simulation, the rotational temperature, T_rot, is determined as 350±150 K ((E_{rot}) =4.4±1.9 kJ mol⁻¹ and the ortho:para ratio, g_{OPR}, estimated to be 3 [which is the statistical equilibrium value above ~60 K (Ref. 26)].

Figure 3(a) shows a TOF spectrum of H₂O(v=0) measured when exciting the 202-321 line of the C−X origin band at 248.514 nm, which is reproduced well by a MB distribution with Ttrans=1800±500 K ((E_{trans}) =29.9±8.3 kJ mol⁻¹). Changing the probe wavelength to excite other transitions, e.g., the C−X, 0₉₀, 2₀₂−2₂₁ line or the blended 3₂₂−3₀₀/3₁₃−2₁₂ lines, caused no discernible change in the TOF spectra. Table I summarizes these results. Figure 1(b) shows the time evolution of the H₂O, C−X, 0₀₀, 2₀₂−2₂₁ line intensity as a function of duration of the 157 nm irradiation. The signal appeared promptly and remained constant during 30 min of subsequent irradiation.

157 nm irradiation of PCI(H₂O) yielded REMPI and TOF spectra of H₂O(v=0) that were essentially identical both in intensity and profile to those obtained from the ASW sample as shown in Figs. 2(b) and 3(b). T_rot is estimated to be 350±150 K ((E_{rot}) =4.4±1.9 kJ mol⁻¹) from the REMPI spectrum [Figs. 2(b) and 2(c)], and a TOF spectrum obtained when exciting the 2₀₂−3₂₁ line of the REMPI spectrum is reproduced with Ttrans=1600±500 K ((E_{trans}) =26.6±8.3 kJ mol⁻¹) [Fig. 3(b)]. The temporal evolution of the H₂O(v=0) signal intensity was also essentially identical to that shown in Fig. 1(b) for the case of H₂O(v=0) from ASW.

B. Photodesorption of D₂O following 157 nm photoirradiation on ASW(D₂O)

Figure 4(a) shows a rotationally resolved REMPI spectrum of part of the C−X 0₀₀ transition of D₂O formed by 157 nm photoirradiation on ASW(D₂O) at 90 K and t=2.5 μs. The best-fit simulation, which assumes T_rot=350±150 K ((E_{rot}) =4.4±1.9 kJ mol⁻¹) and g_{OPR}=2, is shown in Fig. 4(b). Figure 5(a) shows a TOF spectrum of photodesorbed D₂O(v=0) molecules measured when exciting the line at 248.057 nm of the D₂O, C−X, 0₀₀ band (of which the largest contributor is 3₁₃−4₃₁ transition), which is reproduced well by a MB distribution with Ttrans=1800±500 K ((E_{trans}) =29.9±8.3 kJ mol⁻¹). We have also measured TOF spectra for the D₂O line at 247.525 nm for which several lines around J=10 contribute. This TOF spectrum was similar to that when exciting the line at 248.057 nm and reproduced well assuming Ttrans=2000±500 K ((E_{trans}) =33.3±8.3 kJ mol⁻¹). Table I summarizes these results.

C. Photodesorption of D₂O following 193 nm photoirradiation of capped D₂O:H₂S mixed ice layers

193 nm irradiation of pure ASW(H₂O) or ASW(D₂O) resulted in no measurable H₂O or D₂O REMPI signal. 193 nm irradiation of D₂O:H₂S mixed ice layer does result in D₂O(v=0) molecules, however, as illustrated by the TOF spectrum measured when exciting the REMPI line at 247.865 nm (mainly the 1₀₁−2₀₀ transition of the D₂O, C−X, 0₀₀ band) as shown in Fig. 5(b). This TOF spectrum is
reproduced well with \( T_{\text{trans}} = 2250 \pm 750 \) K \((E_{\text{trans}} = 37.4 \pm 12.5 \) kJ mol\(^{-1}\)). The formation of these \( \text{D}_2\text{O}(v=0) \) is assumed to involve initial formation of translationally hot H atoms by 193 nm photolysis of \( \text{H}_2\text{S} \), which induce the subsequent photodesorption of \( \text{D}_2\text{O} \) via the kick-out mechanism. The coverage dependence of the REMPI signal intensity was measured as a function of the dose rate in the range of 10–70 L used to deposit the top \( \text{D}_2\text{O} \) layer. Stronger \( \text{D}_2\text{O} \) signals were observed for thicker top \( \text{D}_2\text{O} \) layers presumably because the lower \( \text{D}_2\text{O} \) exposures did not result in perfectly coverage of the \( \text{H}_2\text{S} \) underlayer. The incomplete coverage was previously obtained in the 193 nm photolysis of \( \text{H}_2\text{O}/\text{D}_2\text{O} \) ice systems, i.e., 30 L exposure of \( \text{H}_2\text{O} \) vapor could cover only the top most \( \text{D}_2\text{O} \) surface layer of the \( \text{ASW}(\text{D}_2\text{O}) \) because of the surface roughness.\(^1\)

We were not able to characterize the rotationally resolved REMPI spectrum for the \( \text{D}_2\text{O} \) molecules as the signal intensity declined steadily during the scan—presumably as a result of depletion of the \( \text{H}_2\text{S} \) and thus of H atoms to induce the kick-out process upon prolonged exposure to 193 nm irradiation.

### IV. MD RESULTS

Details of the MD results of photodesorption following photoexcitation of water ice are described by Andersson et al.;\(^3\)\(^3\)\(^1\)\(^3\) here only details relevant to \( \text{H}_2\text{O} \) desorption will be presented. Photodissociation of a water ice molecule can have several outcomes, with the H and OH photoproducts either becoming trapped in the ice, recombining back to a \( \text{H}_2\text{O} \) molecule, or desorbing from the ice surface. The probability of photodesorption of \( \text{H}_2\text{O} \) is seen to be low, 1.2\% and 0.8\% per absorbed UV photon in the first and second monolayers, respectively, and then decreases with distance from the surface. Analysis of the trajectories shows that there are two distinct mechanisms for the removal of \( \text{H}_2\text{O} \) molecules: (a) *Kick-out mechanism*, an H atom released from photodissociation of \( \text{H}_2\text{O} \) is able to transfer enough momentum to one of the other \( \text{H}_2\text{O} \) molecules to kick it off the surface and (b) *H + OH recombination mechanism*, H and OH promptly recombine to form \( \text{H}_2\text{O} \) and subsequently desorb. In the top two monolayers, both the kick-out and the \( \text{H} + \text{OH} \) recombination mechanisms occur with relative probability ratios of one to four. When photoexcitation occurs in

The solid curve is a fit to the data derived assuming \( T_{\text{trans}}=2250 \) K. The two gray curves show the range spanned by the error bars quoted in Table I.
the third monolayer, the total H₂O desorption probability is 0.4%, and here the kick-out mechanism is dominant, four times more likely than the other mechanism. Because the H₂O molecules are restricted to be rigid, they are by construct considered to be in their vibrational ground states. The recombination process results in the formation of vibrationally excited H₂O molecules, with an average rovibrational energy almost exactly equal to the dissociation limit of H₂O. This should be seen as an upper limit, since the present MD model does not allow energy transfer to the vibrational modes of the surrounding molecules. The lowest calculated rovibrational energy is 173.7 kJ mol⁻¹ above the zero-point energy level. Thus, there was no evidence of desorption of H₂O in the vibrational ground state from the recombination mechanism. We could not observe vibrationally excited H₂O experimentally because of spectroscopic limitations. The calculated average translational and rotational energies of H₂O(υ=0) for the kick-out mechanism is \( T_{\text{trans}} = 1450 \pm 150 \text{ K} \) \((E_{\text{trans}} = 24.1 \pm 2.9 \text{ kJ mol}^{-1}\) \) and \( T_{\text{rot}} = 300 \pm 50 \text{ K} \) \((E_{\text{rot}} = 3.7 \pm 0.6 \text{ kJ mol}^{-1}\) \), respectively. These values are in good accord with the experimental values as shown in Table I.

One interesting observation regarding molecules desorbing via the kick-out mechanism is that their translational energies are much higher than the rotational energies. The likely explanation for this is that the H atom dissociates along the hydrogen bond connecting it to the neighboring H₂O molecule. It thereby hits the O atom and not one of the H atoms, which could lead to (a) reaction or (b) high rotational excitation. Because the H atom hits the H₂O molecule close to the center of mass, most of the energy is transferred into translation and much less into rotation. Hitting the O atom in the H₂O molecule also gives rise to an intermediate H₂O configuration that redissociates into H and H₂O and not to H₂+OH. In the experiments by Yabushita et al., photodesorbing H₂ molecules were observed, which were inferred to be produced from the reaction of H atoms with H₂O molecules. Because the H₂O molecules are restricted to be rigid in the MD simulations, it is at present not possible to study this reaction.

V. DISCUSSION

A. Dependence on water ice morphology

Yabushita et al. previously investigated the photodesorption dynamics of ASW and PCI by analyzing the TOF spectra of photofragment hydrogen atoms following 157 and 193 nm photolysis of the water ice. For ASW, the translational energy of most H atoms was accommodated to the substrate temperature by collisions with bulk water ice before desorption since ASW has a large surface area with micropores. For PCI, on the other hand, the translationally hot H photofragments could desorb from the surface without losing energy by collisions with PCI. However, the present H₂O measurements show little difference in signal intensity or TOF profile when using ASW or PCI samples. This observation suggests that any H₂O molecules that initially desorbed from within the micropores of an ASW sample suffer subsequent collisions with the inside wall of the pore and readorb strongly—by hydrogen bonding with the low temperature surface. As a result, only the translationally hot TOF component that escapes without energy loss through interactions with the internal surface of the voids, i.e., primarily from the top surface of the ASW sample, is observed. Since the effective surface area of the uppermost part of the irradiated sample will be similar for both PCI and ASW, it follows that the REMPI and TOF spectra and the time evolution of the desorbed signal intensity should be similar for ASW and PCI. Even if hot water molecules are produced deep within the bulk phase, they cannot come out to the vacuum as suggested by the MD calculation. Similar behaviors were observed in desorption of OH radicals and O(1D₂ and 3P) atoms following 157 nm photolysis of water ice, i.e., the dominant fraction of OH and O(1D₂ and 3P) products desorbed into vacuum is released from the surface of water ice.

B. Desorption mechanisms of H₂O(υ=0)

We have previously discussed four possible desorption mechanisms under 157 nm photolysis.  

(a) **Kick-out mechanism**: An H atom released by photodissociation of H₂O in the ice transfers enough momentum to another H₂O molecule to cause its ejection from the ice surface.

(b) **H+OH recombination mechanism**: The recombination of photoproduced H and OH species to reform H₂O is highly exothermic (ΔH = -497.1 kJ mol⁻¹) and sufficient to enable subsequent desorption.

(c) **Exciton-mediated mechanism**: Photodesorption associated with excitons in ASW enables transfer of energy from the bulk to near the ice surface and subsequent loss of molecules from the surface. The lowest energy electronic excitation of H₂O has a threshold at ~725 kJ mol⁻¹ (λ ~ 165 nm).

(d) **Reactions of radicals formed by the photodissociation of ice**: The accumulation and diffusion of photoproduced radicals in, or on, the ice are necessary for water desorption to occur as proposed by Westley et al.

Photodesorption mechanisms (b) and (c) are both highly exothermic and can be expected to yield vibrationally hot water molecules. As such, we consider them to be unlikely sources for the H₂O(υ=0) ejection observed in the present experiments. Furthermore, Fig. 1(b) shows that the H₂O(υ=0) desorption from ASW(H₂O) appears promptly after 157 nm irradiation starts, and the desorption yield is independent of 157 nm irradiation time, i.e., the desorption appears to occur without any initial accumulation of photoproduct radicals on the ice surface; hence, mechanism (d) also seems inappropriate. Thus the main photodesorption mechanism for forming H₂O(υ=0) products under the present experimental conditions is likely to be the kick-out mechanism (a), i.e., reaction sequences (1) and (2). Hereafter we concentrate discussion on this kick-out mechanism.
1. H₂O signal intensity change as a function of 157 nm photoirradiation time

The kick-out mechanism can explain the results shown in Fig. 1(b) since the hot H atom is immediately produced after 157 nm photodissociation of ASW and the concentration of hot H atoms should be stable on/in ASW after each 157 nm laser pulse. Yabushita et al. previously observed that the majority of hot H atoms produced by 157 nm photolysis are accommodated by collisions with the ASW sample.14,15 The subsequent formation of H₂ products via a hydrogen abstraction reaction was also observed with the same experimental setup.35,36 H₂ formation by reaction sequence (1)–(5) is an endothermic process, and the activation energy for reaction (5) is estimated to be 132.8 kJ mol⁻¹ from the corresponding gas-phase reaction,42 but the reaction can proceed by virtue of the translational excitation of the hot H atoms formed in the photolysis reaction (1).15,35,36

\[ \Delta H \text{ (kJ mol}^{-1}\text{)} \]

hot H + H₂O(ads) → OH + H₂, 107.3, (5)

Since the kick-out process (a), i.e., reactions (1) and (2), is less endothermic than H₂ formation by reaction sequence (1)–(5), the H₂O molecules hit by H atoms on the ice surface are likely to be desorbed into vacuum.

In contrast, the H+OH recombination process and the reaction of radicals formed by the photodissociation of ice, mechanisms (b) and (d), both depend on radical accumulation at the surface, and their increasing concentration with irradiation time should thus reveal itself by a progressive increase in desorption rate. Indeed, such behavior has been observed for both OH radicals and O atoms that photodesorb via reactions involving radicals.37–39 The results shown in Fig. 1(b) thus suggest that mechanisms (b) and (d) are unlikely to be major sources for desorbed H₂O(ν=0) molecules.

2. 193 nm photoirradiation experiments for D₂O:H₂S mixed ice

The results of the 193 nm photolysis of the D₂O:H₂S mixed ice layers provides further evidence in support of the kick-out mechanism, i.e., reaction (2). The available energy following S–H bond fission in the gas-phase photolysis of H₂S at 193 nm is \( E_{\text{av}} = 238.4 \text{ kJ mol}^{-1} \).13 Khriachtchev et al.43 investigated the 193 nm photolysis of H₂S in solid rare-gas matrices and deduced that (as in the gas phase) this excess energy is largely channeled into H atom translational energy.

H₂O or D₂O REMPI signals were not observed in the 193 nm laser irradiation of neat ASW(H₂O) or ASW(D₂O) consistent with the negligible absorption cross-section of bulk ice at this wavelength. H(D) atoms are formed however, but these are attributed to 193 nm photodissociation of di-merlike H₂O or D₂O structures located at the ice/vacuum interface.14,15,44 Given that they originate from loosely surface-bound species, it is much less likely for such H atoms to induce secondary reactions with neighboring atoms or molecules. Substrate-mediated photodesorption due to the temporary attachment of photo-electrons from the Au substrate is not considered to be a viable mechanism for the present photodesorption of water molecules from the ice surface.10,22

C. Other desorption mechanisms for possible formation of H₂O(ν=1)

The present work strongly suggests that kick-out is the dominant desorption mechanism for H₂O(ν=0) and D₂O(ν=0) molecules following 157 nm photodesorption of ice at 90 K. The present experiments do not exclude the possible formation of vibrationally excited water molecules, however. As argued above, vibrationally excited H₂O molecules might be expected from alternative desorption mechanisms, e.g., the H and OH recombination process (b), or an exciton mediated process (c). We tried to search for REMPI signals of H₂O(ν≥1), but no evidence for H₂O(ν≥1) products was obtained, most likely reflecting the limitations of the spectroscopy used. Hence, the other desorption mechanisms will be briefly discussed in the context of possible photodesorption of vibrationally excited H₂O(D₂O) molecules.

1. H and OH recombination process

The MD calculations suggest that H atoms could also recombine with OH radicals, and the resulting H₂O molecule subsequent desorb as the recombination is highly exothermic.3,31 The vuv photolysis studies of Yabushita et al.35,36 deduced that H₂ formation at a water ice surface at 90 K was attributable to the highly exothermic recombination of photolytically produced H atoms. H₂O₂ formation on a water ice surface has also been observed35 presumably from the recombination of photolytically produced OH radicals. These results serve to encourage the view that photolysis leads to desorption of H₂O molecules in excited vibrational levels via the H+OH recombination mechanism.

2. An exciton-mediated process

The optical depth of ASW at 157 nm is ~100 nm,41 so the photon energy available for reaction is primarily absorbed in the bulk of the water ice. A qualitative depiction of the band structure of ice has been reported by Kimmel et al.46 Excitons associated with the 4a₁ ← 1b₁ transition in condensed water have been implicated in a low-energy electron stimulated reaction, which could enable transfer of energy from the bulk to near the ASW surface.30,45 Kimmel and co-workers found experimental support for the concept of mobile excitons in ASW that initiate reactions at the ASW/vacuum interface.20,21,47,48 Significant vibrational excitation might be anticipated if the excess energy from the electronic excitation was deposited into an H₂O molecule that desorbed as a result of such a mechanism.

VI. SUMMARY

The translational and rotational energies of water molecules (H₂O and D₂O, in their ground vibrational state) desorbed following 157 nm excitation of amorphous solid water and polycrystalline ice have been measured. The measured energy distributions are in good accord with those
predicted by classical molecular dynamics calculations for the kick-out mechanism, i.e., the ejection of a water molecule from the ice surface by a hot hydrogen (deuterium) atom formed by photodissociation of a neighboring water molecule. Desorption of D$_2$O following 193 nm photodissociation of a D$_2$O/H$_2$S mixed ice was investigated also for additional direct evidence of the operation of the kick-out mechanism. The ortho:para ratios of the photodesorbed H$_2$O and D$_2$O products (3:1 and 2:1, respectively) are appropriate for the measured Boltzmann rotational distributions.
