ABSTRACT

Background HLA-DRB1 is associated with rheumatoid arthritis (RA). However, it has recently been suggested that HLA-DRB1 is only associated with patients with RA who have anticitrullinated peptide/protein antibodies (ACPA), which are specific to RA.

Objective To elucidate whether specific HLA-DR alleles are associated with ACPA-negative RA development.

Methods HLA-DRB1 typing was carried out in 368 Japanese ACPA-negative patients with RA and 1508 healthy volunteers as the first set, followed by HLA-DRB1 typing of 501 cases and 500 controls as the second set. The HLA-DRB1 allele frequency and diplotype frequency were compared in each group, and the results of the two studies were combined to detect HLA-DRB1 alleles or diplotypes associated with ACPA-negative RA.

Results HLA-DRB1*12:01 was identified as a novel susceptibility allele for ACPA-negative RA (p = 0.00088, OR = 1.72, 95% CI 1.31 to 2.26). HLA-DRB1*04:05 and *14:03 showed moderate associations with ACPA-negative RA (p = 0.0063, OR = 1.26, 95% CI 1.07 to 1.49 and p = 0.0043, OR = 1.81, 95% CI 1.20 to 2.73, respectively). The shared epitope was weakly associated with ACPA-negative RA, but no dosage effect was detected (p = 0.016, OR = 1.17, 95% CI 1.03 to 1.34). A combination of HLA-DRB1*12:01 and DRB1*09:01 showed a strong association with susceptibility to ACPA-negative RA (p = 0.00013, OR = 3.62, 95% CI 1.79 to 7.30). Homozygosity for HLA-DR8 was significantly associated with ACPA-negative RA (p = 0.0070, OR = 2.16, 95% CI 1.22 to 3.82). It was also found that HLA-DRB1*15:02 and *13:02 were protective against ACPA-negative RA (p = 0.00010, OR = 0.68, 95% CI 0.56 to 0.83 and p = 0.00059, OR = 0.66, 95% CI 0.52 to 0.84, respectively).

Conclusions In this large-scale association study multiple alleles and diplotypes were found to be associated with susceptibility to, or protection against, ACPA-negative RA.

INTRODUCTION

Rheumatoid arthritis (RA) is one of the most common causes of chronic arthritis and results in severe joint damage and a shorter life span.1 Genetic factors have been shown to contribute to the onset of RA.3 Among the genetic susceptibility loci detected to date, HLA-DRB1 has a strong impact on the predisposition to RA and has been repeatedly shown to be associated with RA in an ethnicity-independent manner.3 It is widely accepted that the shared epitope (SE), a common amino acid sequence located from the 70th to the 74th amino acids of the HLA-DR β chain, explains the associations of specific HLA-DRB1 alleles with RA.4 Anticitrullinated protein antibodies (ACPA) are a highly specific marker of RA.5 6 Recent data have shown that the SE is associated with ACPA-positive RA but not associated or only weakly associated with ACPA-negative RA.7-9 Many of the non-HLA susceptibility genes for RA detected repeatedly show a strong association with susceptibility to, or protection against, ACPA-negative RA.10 11 In Asian populations, there has only been a small study which showed that HLA-DRB1*09:01 might be associated with ACPA-negative RA,15 while SEs, especially DRB1*04:05, *04:01 and *01:01, were associated with RA and ACPA-positive RA.15 16 Thus, no specific alleles that convey susceptibility to, or are protective against, ACPA-negative RA have been identified in populations of European or Asian descent. In this large-scale Japanese case–control association study, we show that HLA-DRB1*12:01, *14:03 and *04:05 are susceptibility alleles for ACPA-negative RA and that HLA-DRB1*13:02 and *15:02 are protective against ACPA-negative RA. We also identified multiple diplotypes that convey susceptibility to, or are protective against, ACPA-negative RA.

MATERIALS AND METHODS

Study subjects

DNA samples were collected at Kyoto University Hospital from 184 patients with RA who were negative for ACPA, as reported previously,7 and another 184 patients with RA without ACPA were recruited at Tokyo Women’s Medical University. These two sample groups were used as the first
set. Independent DNA samples were collected from 501 ACPA-negative patients with RA at RIKEN under the support of BioBank Japan and were used as the second set. The 501 cases in the second set are a fraction of 2410 RA cases included in another manuscript (K Shimane et al, unpublished data). All patients were Japanese and diagnosed by rheumatologists to fulfill the 1987 American College of Rheumatology revised criteria for RA.17 A first set of control DNA samples were collected from 1508 healthy control subjects at Aichi Cancer Center Hospital and from the DNA banks of the Pharma SNP Consortium, which contains DNA samples from healthy Japanese volunteers.18 The second set of control DNA samples were collected from 500 healthy volunteers at the HLA laboratory. This study was approved by the local ethical committees at each institution, and written informed consent was obtained from all patients. Basic information about cases and controls is shown in table 1.

**ACPA detection**

ACPA were detected with the MESACUP CCP ELISA kit (Medical and Biological Laboratories Co, Ltd, Nagoya, Japan) according to the manufacturer’s instructions at each institution. A cut-off value of 4.5 U/ml was used to assess ACPA positivity.

**HLA-DRB1 genotyping**

HLA-DRB1 typing was carried out with the WAKFlow system and described in detail elsewhere.7 In the 184 cases collected at Kyoto University and all the controls in the two sets, genotyping was performed at the HLA laboratory (Kyoto, Japan), whereas it was carried out at RIKEN for all 501 cases in the second set. HLA-DRB1 genotyping of the 184 cases collected at Tokyo Women’s Medical University was performed by a sequencing-based typing method using the AlleleSEQR HLA-DRB1 typing kit (Abbott, Tokyo, Japan), and allele assignment was performed using the Assign software.

**Statistical analysis**

The frequency of each genotype or diplotype among the ACPA-negative patients with RA was compared with that in the controls using a χ² test or Fisher’s exact test. Ninety-five percent CIs, p values and ORs were also calculated. The relative risk (RR) of ACPA-negative susceptibility induced by homozygosity for each allele was calculated to estimate the dosage effect. We performed 1000 permutation tests to confirm the associations found for each allele. Logistic regression analysis was used to evaluate the effects of alleles by adjusting for the influence of other alleles. Statistical analysis was performed using the R statistic system (http://www.R-project.org) or SPSS (version 18). The power calculation was performed using an online power calculator (http://pngu.mgh.harvard.edu/~purcell/gpc/).

### RESULTS

**Genotyping of the first set**

We performed HLA-DRB1 genotyping in the 368 ACPA-negative patients with RA and 1508 healthy controls in the first set to compare the allele frequency of each genotype between the cases and controls (table 1). Tables 2 and 3 show the main results of our association study for single alleles and diplotypes, respectively. More detailed results are given in the online supplementary tables 1 and 2.

The SE showed a weak association with moderate effect (p=0.039), mainly due to HLA-DRB1*04:05. Among the other HLA-DRB1 alleles, HLA-DRB1*14:03, *12:01, and *09:01 resulted in moderate to potential susceptibility to ACPA-negative RA (p=0.022, 0.10, and 0.10, respectively). DRB1*13:02, *04:03, and *15:02 showed moderate to potentially protective effects (p=0.0072, 0.059, and 0.12, respectively).

**Replication in the second set and combined analysis**

We performed HLA-DRB1 genotyping of samples in the second set to replicate the results found in the first set, using the DNA samples from 501 ACPA-negative patients with RA and 500 sex-matched healthy controls and combined the results of the two association studies.

Among the susceptibility alleles found in the first set, HLA-DRB1*12:01 was confirmed to display a susceptible association (p=0.010 and 0.00008 for the second set and combined study, respectively; table 2). The susceptibility tendencies of *04:05 and *14:03 were replicated in the second set, and these alleles showed moderate associations with susceptibility to ACPA-negative RA in the combined analysis (p=0.0063 and 0.0043, respectively). DRB1*09:01 and *14:05 showed potential susceptibility to ACPA-negative RA in the pooled study (p=0.062 and 0.080, respectively). The SE showed a weak association with susceptibility to ACPA-negative RA in the combined study (p=0.016), but we could not detect any dosage effect (table 3 and figure 1). Among the protective alleles detected in the first set, the protective effect of DRB1*15:02 was successfully replicated (p=0.002 and 0.00010 in the second set and combined study, respectively; table 2). Although the protective effect of DRB1*13:02 was not replicated in the second set, the combined analysis showed a significant protective effect (p=0.00059). The protective effect of DRB1*04:05 was confirmed in the second set, and the combined study demonstrated a weak protective association (p=0.058). To exclude the possibility that the associations of the susceptibility alleles were induced by the absence of protective alleles or vice versa, we applied logistic regression analysis. The logistic regression analysis suggested that none of the allelic associations—namely, those of HLA-DRB1*12:01, *14:03, *04:05, *13:02, and *15:02, depended on the effects of other alleles (online supplementary table 3). In addition, the permutation tests confirmed the associations of these five alleles (permutation p<0.0070, data not shown).

Next, we analysed the dosage effects of each protective or susceptibility allele. DRB1*12:01 showed a potential dosage effect, but only two patients were homozygous for DRB1*12:01 (figure 1). We could not detect any dosage effects of HLA-DRB1*04:05 or the SE. No patients were homozygous for *14:03

Allele number and the frequency of each HLA-DRB1 allele in ACPA-negative patients with RA (n=368 and allele number=736 in the 1st set and n=501 and allele number=1002 in the 2nd set) and healthy controls (n=1508 and allele number=3016 in the 1st set and n=500 and allele number=1000 in the 2nd set) as well as the p value and OR of each allele for the development of ACPA-negative RA are shown. p Values were calculated using Fisher’s exact test or the χ² test.

*Percent of allele frequency.

ACPA, anticitrullinated peptide/protein antibody; SE, shared epitope; RA, rheumatoid arthritis.

in the cases or controls. Both DRB1*13:02 and *15:02 showed potential dosage effects.

Diploptyle analysis

When we analysed the effects of HLA-DRB1 allele diploptypes on the predisposition to ACPA-negative RA, we found that a combination of DRB1*09:01 and *12:01 demonstrated susceptible effects in both sets (p=0.025, 0.020 and 0.00013 in the first, second and combined study, respectively; table 3). DRB1*08:03 homozygosity showed a weak susceptible association without any dosage effects (table 3, supplementary table 1). Although we found no susceptibility effect of DRB1*08:02 homozygosity, the combination of DRB1*08:02 and *08:03 also resulted in weak susceptibility (supplementary table 2). When we analysed DR8 allele homozygosity, we found that it displayed a moderate susceptibility association in the combined analysis (p=0.0070, table 3). Any combination of two of the three susceptibility alleles—namely, HLA-DRB1*12:01, *14:03, and *04:05, showed a potentially susceptible effect (supplementary table 2).

The HLA-DRB1*08:03 and *15:02 diploptyle showed the strongest protective effect (p=0.00011, table 3). We found that the diploptyles with protective effects (*08:03*/15:02, *15:02*/15:02 and *13:02*/15:02) all included HLA-DRB1*15:02 (table 3).

DISCUSSION

Recent studies have suggested that ACPA-negative RA is a genetically different subset of RA.7 8 While SE is very strongly associated with ACPA-positive RA, it is reported as not associated or only weakly associated with ACPA-negative RA. In populations of European descent, HLA-DR3 and DR13 were reported to be susceptibility alleles,12 13 but a recent meta-analysis of a large Caucasian cohort did not find any such association.14 In Japanese subjects, only DRB1*09:01 was reported to be associated with ACPA-negative RA, using small numbers of patients and controls (28 and 265, respectively).15 16 HLA-DR3 is rare in the Japanese population, and we found only one HLA-DR3 allele in our cohorts.

Although genetic factors contribute to the development of ACPA-negative RA as much as ACPA-positive RA,15 little is known about the ACPA-negative RA susceptibility alleles of HLA and non-HLA genes.

Here, we performed a case–control association study using a large number of ACPA-negative patients with RA and controls and showed that multiple alleles and diploptyles are associated with ACPA-negative RA.
Extended report

with ACPA-negative RA in Japanese people. Although the con-
trols in the first set had different age and sex ratio values from
those of the patients and we could not obtain age data for the
500 controls in the second set, the effects of the above-men-
tioned difference and lack of data on our results were considered
to be limited. The HLA locus is located on chromosome 6 and
is not affected by sex or age. Indeed, regression analysis did not
significantly alter our association results (data not shown).

Our study showed that HLA-DRB1*12:01 is strongly associ-
ated with ACPA-negative RA and that HLA-DRB1*14:03 and
HLA-DRB1*04:05 in SE are moderately associated with ACPA-
negative RA in Japanese people. All three susceptibility alleles
showed susceptibility associations with ACPA-negative RA
when found in combination with one of the other two alleles.

Our data also suggested a dosage effect of HLA-DRB1*12:01,
while no dosage effect of HLA-DRB1*04:05 was detected, with
decreased OR of DRB1*04:05 in homozygotes compared with
heterozygous patients. In addition, we showed that the HLA-
DRB1*09:01 and HLA-DRB1*12:01 diplotype and HLA-DR8
homozygosity are strong susceptibility combinations for ACPA-
negative RA. We also determined HLA-DRB1*13:02 and *15:02
as protective alleles against ACPA-negative RA with a potential
dosage effect. The combination of DRB1*08:03 and *15:02 had
a strong protective effect in our study. Using logistic regression
analysis, we confirmed that the effects of these susceptibility
and protective alleles do not depend on each other (supple-
mentary table 3).

Although we searched for common amino
acid sequences among the susceptibility alleles, we could not
detect any meaningful sequences common to HLA-DRB1*12:01,
*14:03, and/or *04:05. We also failed to detect a common amino
acid sequence among the protective alleles HLA-DRB1*15:02
and *13:02.

Although the association of SE with ACPA-negative RA can-
not be concluded in our large-scale study showed that it really
is not associated with the SE in ACPA-negative RA. As we observed a lower
OR of the SE in ACPA-negative RA than in ACPA-positive RA, our results do not
suggest that SE is associated with ACPA-negative RA. However, the absence of an
association does not rule out the possibility that SE is involved in the pathogenesis of ACPA-negative RA. Further studies are needed to clarify the role of SE in ACPA-negative RA.

Diploidy number and the frequency of each HLA-DRB1 diplotype in ACPA-negative patients with RA (n=368 and 501 in the 1st and 2nd set, respectively) and healthy controls (n=1508 and 500 in the 1st set and 2nd set, respectively) as well as the p value and OR of each diplotype for the development of ACPA-negative RA are shown. p Values were calculated using Fisher’s exact test or the χ² test.

1 Number of alleles (allele frequency).

ACPA, anticitrullinated peptide/protein antibody; SE, shared epitope; RA, rheumatoid arthritis.

### Figure 1

Suggestive dosage effect of associated alleles on anticitrullinated peptide/protein antibody (ACPA)-negative rheumatoid arthritis susceptibility. The OR for each diplotype is shown. Different colours indicate the number of copies of each allele. The numbers of homozygotes of *12:01, *14:05, *15:02 and *13:02 in cases and controls in the first set had different age and sex ratio values from those in the second set. The figures indicate the OR for each diplotype for the development of ACPA-negative RA. The OR for each diplotype was calculated using logistic regression analysis. Our results showed that HLA-DRB1*12:01 and HLA-DRB1*14:05 in SE are strongly associated with ACPA-negative RA in Japanese people. All three susceptibility alleles showed susceptibility associations with ACPA-negative RA when found in combination with one of the other two alleles. Our data also suggested a dosage effect of HLA-DRB1*12:01, while no dosage effect of HLA-DRB1*04:05 was detected, with decreased OR of DRB1*04:05 in homozygotes compared with heterozygous patients. The combination of DRB1*08:03 and *15:02 had a strong protective effect in our study. Using logistic regression analysis, we confirmed that the effects of these susceptibility and protective alleles do not depend on each other.
allele frequency of HLA-DRB1*12:01 in a European population

Only two homozygous patients were among the cases. The possible dosage effect, further confirmation is necessary as a potential common risk allele for both T1D and ACPA-negative RA is interesting. Although HLA-DRB1*12:01 showed a strong protective effect against ACPA-negative RA, HLA-DRB1*04:03, it showed a potentially protective effect against ACPA-negative RA susceptibility. While association studies using ACPA-negative patients with RA and the detection of multiple alleles and diplotype associated with susceptibility to, or protection against, ACPA-negative RA. To evaluate whether our cohort had sufficient power to detect HLA-DRB1 genotype associations, we applied a risk allele with 5% frequency in the general population (see ‘Materials and methods’). Our power calculation showed that this study had power values of 81% for finding genotype associations with an OR of 1.4 at the 0.05 significance level. When we set the OR to 1.2, our study had power values of 31%. These results suggest that our study has sufficient power to detect associated alleles that are present in relatively high frequencies (such as 5%) and a moderate OR of 1.4. On the contrary, our study has insufficient power to detect associations involving a weak OR such as 1.2. There is a possibility that ACPA-negative RA is associated with more HLA-DRB1 alleles or diplotype that display a low allele frequency and/or low power. Further studies using ACPA-negative RA samples in Japan are necessary to find such associations.

While association studies using ACPA-negative patients with RA of European descent only found a few weak associations and none of them were subsequently replicated, our study successfully determined multiple alleles with relatively strong effects on ACPA-negative RA. From this viewpoint, we suppose that Japanese ACPA-negative patients with RA have a relatively similar genetic background compared to European patients. Population stratification within European population may also be assumed. Nevertheless, the validation of our results in Asian countries is necessary, and large-scale genome-wide association studies of ACPA-negative RA are also required to elucidate the pathogenesis of ACPA-negative RA.

As DRB1*09:01 has been shown to be associated with a decreased ACPA titre in ACPA-positive RA, it is likely to be associated with ACPA-negative RA. While DRB1*09:01 showed a potential susceptibility association (p=0.062), the combination of DRB1*09:01 and *12:01 showed strong susceptibility association (p=0.00013). DRB1*09:01 also showed a possible dosage effect. From this viewpoint, we consider that DRB1*09:01 has a potential susceptibility effect on ACPA-negative RA. Owing to the relatively high allele frequency of DRB1*09:01, another independent association study or appropriate classification of ACPA-negative RA could produce significant results.

In addition to the different associations of the SE with ACPA-negative RA and ACPA-positive RA, we found multiple alleles associated with ACPA-negative RA that are not shared by ACPA-positive RA. These showed that ACPA-negative RA is a distinct subset of RA. Moreover, when we focused on ACPA-negative erosive RA to exclude the possibility of our results being affected by non-RA arthritic diseases, the effects of all the following alleles were maintained: *12:01, *14:03, *04:05, *13:02 and *15:02 (data not shown).

This is the first large-scale association study involving Japanese ACPA-negative patients with RA and the detection of multiple alleles and diplotype associated with susceptibility to, or protection against, ACPA-negative RA. While association studies using ACPA-negative patients with RA of European descent only found a few weak associations and none of them were subsequently replicated, our study successfully determined multiple alleles with relatively strong effects on ACPA-negative RA. From this viewpoint, we suppose that Japanese ACPA-negative patients with RA have a relatively similar genetic background compared to European patients. Population stratification within European population may also be assumed. Nevertheless, the validation of our results in Asian countries is necessary, and large-scale genome-wide association studies of ACPA-negative RA are also required to elucidate the pathogenesis of ACPA-negative RA.

Acknowledgements The authors thank Dr Naohiro Yukawa, Dr Hajime Yoshifuji, Dr Daisuke Kawabata, Dr Takaki Nojima, Dr Takashi Usui and Dr Takao Fuji at Kyoto University for collecting the DNA samples. We thank Mr Taishi Shigeki for developing the clinical database software used in Dohgo Spa hospital. We also thank all the doctors and medical staff who collected the patients’ samples. This study was performed under the support of Genetics and Allied research in Rheumatic diseases Networking (GARNET) consortium.
