Abstract

Ghrelin, a natural ligand for the growth hormone (GH)-secretagogue receptor (GHS-R), is now known to play a role in a number of different physiological processes. For example, ghrelin increases GH secretion, feeding, and body weight when administered centrally or peripherally. These unique effects of ghrelin should be invaluable for the development of novel treatments and disease diagnostic techniques. Clinical trials have already been performed to assess the utility of ghrelin for the treatment of several disorders including anorexia, cachexia, and GH-related disorders. This review summarizes the recent advances in this area of research.
1. Introduction

Ghrelin is a peptide hormone that was discovered in 1999 as an endogenous ligand for the growth hormone (GH)–secretagogue receptor (GHS-R) [1]. Ghrelin is a 28-amino-acid peptide and possesses a unique fatty acid modification, n-octanoylation, at Ser 3. There are two circulating forms of ghrelin, acylated and unacylated (desacyl), and the acylated form is essential for ghrelin’s biological activity through GHS-R. Recently, however, desacyl ghrelin was reported to influence both cell proliferation and adipogenesis through another unknown receptor [2-5]. Ghrelin is produced primarily in the stomach and circulates in the blood at a considerable plasma concentration. Expression of ghrelin is also detectable in the hypothalamus, intestine, pituitary, placenta, and other tissues [1, 6-8]. Ghrelin is now known to play a role in a number of different physiological processes; for example, ghrelin increases GH secretion and feeding, and decreases insulin secretion [1, 9-19].

These unique effects of ghrelin and growth hormone secretagogues (GHS) should be invaluable for the development of novel treatments and disease diagnostic techniques [20-22]. Clinical trials have already been performed to assess the utility of ghrelin for the treatment of various disorders including anorexia [23-26], cachexia [27-29], malnutrition [30], GH-related disorders [31], and postgastrectomy/esophagectomy [32,
Because many excellent reviews concerning basic and clinical research on ghrelin have already been published, we will summarize and discuss recent clinical trials of ghrelin in this work.

2. Physiological actions of ghrelin

2.1. Orexigenic action

Ghrelin has a well-established role in stimulating appetite and increasing food intake [34, 35]. Peripheral administration of ghrelin stimulates GH secretion and appetite in both animals and humans [10, 18]; it is the only hormone known to have this effect. Ghrelin increases c-fos expression in the arcuate nucleus, and also activates hypothalamic neuropeptide Y (NPY)/Y1 receptors and agouti-related peptide (AgRP) pathways [36-38]. In addition, ghrelin induces food intake via the orexin pathway [39]. These functions are mediated at least in part by vagal nerve pathways [40]. Repeated administration of ghrelin resulted in significant weight gain in rats [41] and patients with chronic obstructive pulmonary disease (COPD) [28].

2.2. Stimulation of GH secretion

Ghrelin strongly stimulates GH secretion in humans [12, 16, 17, 42], several-fold more potently than GHRH under similar conditions. Furthermore, ghrelin and growth
hormone releasing hormone (GHRH) synergistically increase GH release [17]. Ghrelin might also play a role in GH release in a non-acute setting [43, 44]. GH regulates IGF-I levels, promotes anabolism, and increases muscle strength [45, 46]. While GH enhances lipolysis, IGF-1 stimulates protein synthesis, myoblast differentiation, and muscle growth.

2. 3. Anti-inflammatory action

Evidence that ghrelin exerts anti-inflammatory actions has been accumulating. Ghrelin suppresses the production of proinflammatory cytokines, including IL-1β, IL-6, and TNF-α both in vitro [47, 48] and in vivo [49-51]. In clinical trials, daily administration of ghrelin for three weeks decreased inflammatory cytokine levels and neutrophil density in sputum from patients with chronic respiratory infections [52]. In contrast, ghrelin induces the anti-inflammatory cytokine IL-10 [49, 53].

Ghrelin inhibits the activation of NF-κB, a transcription factor known to control the production of multiple pro-inflammatory cytokines during inflammatory insults [48, 50, 53]. Although the molecular mechanisms and cellular targets mediating ghrelin inhibition of NF-κB activation remain to be determined, the vagus nerve may play an important role in the ghrelin-mediated inhibition of pro-inflammatory cytokine release [50, 54]. Cachexia and muscular wasting occur via protein degradation by the
ubiquitin–proteasome pathway [55]. Two muscle-specific ubiquitin ligases, muscle
RING-finger protein-1 (MuRF1) and atrogin-1/muscle atrophy F-box (MAFbx), are up-
regulated under catabolic conditions. NF-κB activation may regulate skeletal muscle
proteasome expression and protein degradation. The elevation in MuRF1 and MAFbx
expression seen in skeletal muscle after thermal injury, arthritis, and dexamethasone
administration were normalized, attenuated, and prevented, respectively, by ghrelin or
GHS administration [56-58]. IGF-1 prevents the expression of MuRF1 and MAFbx by
inhibiting Forkhead box O (FOXO) transcription factors via stimulation of the
phosphatidylinositol-3-kinase (PI3K)/Akt pathway. The IGF-1 receptor triggers
activation of several intracellular kinases, including phosphatidylinositol-3-kinase
(PI3K) [59]. Thus, the effects of ghrelin on NF-κB activation and IGF-1 synthesis are
favorable for minimizing inflammatory responses and sarcopenia in patients with
cachexia.

2.4. Other actions

The role of ghrelin in stimulating gastric emptying and acid secretion is well-
established [60]. This effect may ameliorate gastrointestinal symptoms in patients with
anorexia–cachexia syndrome. Ghrelin also increases endogenous nitric oxide (NO)
release [61, 62], which may influence its orexigenic and anti-inflammatory actions [63,
3. Potential clinical applications of ghrelin

3.1. Appetite-related disorders

3.1.1. Anorexia nervosa (AN) and related disorders

Anorexia nervosa (AN) is an eating disorder characterized by chronically decreased caloric intake, resulting in self-induced starvation. Plasma ghrelin levels are elevated in lean patients with anorexia nervosa, consistent with a state of negative energy balance [65-67]. Only a few preliminary studies have been performed to examine the effects of ghrelin in individuals with AN. Miljic et al. infused ghrelin (300-min intravenous infusion of 5 pmol/kg/min ghrelin) into nine AN patients with very low body weights, six AN patients who had partially recovered their body weights but who remained amenorrheic, and ten constitutionally thin female subjects [68]. The fifteen AN patients felt significantly less hungry compared with the constitutionally thin subjects, suggesting that AN patients are less sensitive to the orexigenic effects of ghrelin than healthy controls. In another paper, however, six of nine patients with restrictive AN were reported to have been hungry after ghrelin administration (1.0 µg/kg as an intravenous bolus), a similar ratio to that seen in normal subjects (five of
seven) [69]. We examined the effects of ghrelin on appetite, food intake, and nutritional parameters in AN patients [26]. Five female patients who met the Diagnostic and Statistical Manual IV (DSM-IV) criteria for restricting-type AN [70] and desired to recover from the disorder participated in this study. The patients were hospitalized for 26 days (6 days pre-treatment, 14 days ghrelin infusion, and 6 days post-treatment). The patients received an intravenous infusion of 3 μg/kg ghrelin twice a day (before breakfast and dinner). Attitudes toward food were evaluated by visual analogue scale (VAS) questionnaires and daily energy intake was calculated by dieticians. Ghrelin infusion improved epigastric discomfort or constipation in four patients, whose hunger scores on VAS also increased significantly after ghrelin administration. Daily energy intake during ghrelin administration increased by 12–36% compared with the pre-treatment period. The change in body weight of the five patients ranged from +1.5 to 2.4 kg. Nutritional parameters such as total protein and triglyceride levels improved. There were no serious adverse effects, including psychological symptoms. All patients who did not gain weight during hospitalization did so after discharge. These findings suggest that ghrelin may have therapeutic potential in AN patients who cannot gain weight because of gastrointestinal dysfunction. Clearly, further studies, including randomized controlled trials, are needed to determine whether ghrelin is useful for the
treatment of AN.

Functional dyspepsia (FD) is a disorder characterized by the presence of chronic or recurrent symptoms of upper abdominal pain or discomfort [71]. Although no known specific organic abnormalities are present in FD, abnormalities in gastrointestinal motility and sensitivity are thought to play a role in a substantial subgroup of patients. In addition, some patients suffer from anorexia and body-weight loss. We found that levels of plasma acylated, but not desacyl, ghrelin correlated with a subjective symptom score in FD patients, suggesting that acylated ghrelin may play a role in the pathophysiology of FD [72]. We attempted to evaluate the clinical response to repeated ghrelin administration in patients with anorexia caused by functional disorders, such as FD and ‘other eating disorders’ or ‘unspecified eating disorders’ [24]. The inclusion criteria in this study were subjects who 1) were diagnosed with functional anorexia, including FD or other eating disorders with the exception of anorexia nervosa, 2) were lean (BMI < 22 kg/m²), and 3) exhibit decreased food intake. Subjects received an intravenous infusion of ghrelin for 30 minutes twice a day (before breakfast and dinner) for two weeks, and we investigated the effects on food intake, appetite, hormones, and metabolic parameters. Six patients with FD were enrolled in this study. Ghrelin administration tended to increase daily food intake in comparison to levels before and
after completion of treatment, but this difference, which was the primary endpoint of the study, did not reach statistical significance. Hunger sensation was significantly elevated at the end of drip infusion. No severe adverse effects were observed. These results suggest that ghrelin administration is safe and that this treatment has stimulatory effects on appetite in patients with FD. Further studies remain necessary to confirm the efficacy of ghrelin treatment for anorexia-related disorders.

3.1. 2 Cachexia and related disorders

A number of trials seeking to utilize ghrelin for the treatment of cachexia have recently been performed [73]. These studies have sought to evaluate ghrelin as a treatment for patients with cachexia associated with congestive heart failure (CHF), COPD, cancer, and End-stage renal disease (ESRD). Cachexia manifests as excessive weight loss in the setting of an underlying chronic disease [74], and is typically associated with anorexia as a major cause of weight loss. Weight loss and decreased appetite are the major causes of morbidity and mortality in patients with anorexia–cachexia syndrome. There is an immediate need for effective, well-tolerated treatments to stimulate appetite [75], prompting several trials to explore the application of ghrelin as a treatment for patients with cachexia.
3.1.2.1. CHF-associated cachexia

Ghrelin induces a positive energy balance state through both GH-dependent and -independent mechanisms and has protective cardiovascular effects [76]. GH treatment may be especially useful in a subgroup of patients with cardiac cachexia [77]. Ghrelin stimulates food intake, induces adiposity, regulates the central nervous system to decrease sympathetic nerve outflow, and inhibits apoptosis of cardiomyocytes and endothelial cells in a GH-independent manner. Nagaya et al. investigated the effects of ghrelin on cardiac cachexia in 10 patients with CHF [27] (Table 1). Daily administration of ghrelin for three weeks increased both food intake and body weight. This study also demonstrated improvements in patient exercise capacity, muscle wasting, and left ventricular function. Ghrelin treatment also resulted in significantly decreased plasma norepinephrine levels. Although this study was neither randomized nor placebo-controlled, the eight CHF patients who did not receive ghrelin (control group) were followed to rule out any time-course effects during hospitalization. None of the aforementioned parameters changed in patients with CHF who did not receive ghrelin therapy. Further studies will be necessary to identify the pathways involved in this use of ghrelin and to determine the best therapeutic strategies for ghrelin use to combat the wasting process found in cardiac cachexia patients [77]. Clinical trials are currently
attempting to reproduce these data in a double-blind, placebo-controlled fashion.

3.1.2. COPD-associated cachexia

Patients with COPD often exhibit some degree of cachexia [78], which is an independent risk factor for mortality in COPD; GH treatment increases muscle mass in such patients. COPD and CHF are both associated with multiple pathophysiological disturbances, including anemia and neurohormonal activation [79]. In COPD patients, ghrelin exhibits anti-inflammatory effects. Chronic respiratory infections, characterized by neutrophil-dominant airway inflammation, lead to end-stage cachexia [80]. The cytotoxicity of accumulated neutrophils against bronchial and alveolar epithelial cells induces a deterioration of pulmonary function in COPD, resulting in excess energy expenditure and weight loss in patients. Intravenous ghrelin treatment for three weeks reduced neutrophil counts in sputum samples as well as the volume of sputum, suggesting that ghrelin suppressed excess neutrophil influx [52].

An open-label pilot study examined the ability of ghrelin to improve cachexia and functional capacity in patients with COPD; ghrelin was administered intravenously for three weeks to seven cachectic patients with COPD [28]. Repeated ghrelin administration significantly increased food intake, body weight, lean body mass, and peripheral and respiratory muscle strength. Ghrelin treatment ameliorated exaggerated
sympathetic nerve activity, as indicated by marked decreases in plasma norepinephrine levels. Subsequently, another placebo-controlled trial demonstrated that ghrelin increased both appetite and body weight with an apparent dose-dependent trend towards improved physical performance (chair stand score) [81]. A larger clinical trial is currently being conducted to confirm these data in a double-blind, placebo-controlled fashion. Comparisons of this treatment to current standard medications will be required [79].

3.1.2.3. Cancer cachexia

Anorexia is frequently encountered in cancer patients, and is one of the major causes of malnutrition and cachexia in this patient population. Ghrelin administration resulted in significant increases in weight and food intake in rodent models of cancer-associated cachexia [82-84]. DeBoer et al. determined that weight gain resulted from a reversal in the loss of lean body mass, a critical component of cachexia [82].

Several randomized, double-blind placebo-controlled trials have demonstrated the efficacy and safety of ghrelin or GHS in patients with cancer-associated cachexia [23, 25, 85]. Nearry et al. performed a randomized, placebo-controlled, cross-over clinical trial to determine whether ghrelin could stimulate appetite in seven cancer patients with severe anorexia [23]. Ghrelin infusion resulted in a marked increase in energy intake in
comparison to saline-treated controls; all patients in the study demonstrated increased food consumption. The meal appreciation score was also higher in ghrelin-treated individuals. Strasser et al. detailed a randomized, double-crossover, phase 1/2 study in 21 patients with advanced cancer [25]. They infused a low or high dose of ghrelin or placebo before lunch daily for four days in each course. Nutritional intake and eating-related symptoms did not differ between the ghrelin- and placebo-treated groups. More patients, however, preferred ghrelin to placebo at the middle and end of the study, although this finding was not dose-dependent. In contrast to the results of Neary et al., this study did not demonstrate any increases in food intake. As the patient characteristics and study designs were very different in the two studies, further investigation is required.

An important concern regarding the use of ghrelin in cancer-associated cachexia is that ghrelin may increase the levels of growth factors, such as GH and IGF-1, that stimulate tumor growth. Additionally, ghrelin itself may have mitogenic potential. As far as we know, no in vivo data has examined the differences in tumor growth following ghrelin or GHS treatment. Long-term, large-scale clinical trials are required to determine whether ghrelin treatment promotes tumor growth.

3.1.2.4. End-stage renal disease (ESRD)
ESRD is a chronic condition frequently associated with nutritional dysfunction [86]. This type of malnutrition is highly resistant to intervention and is a major predictor of morbidity and mortality for patients on either peritoneal dialysis (PD) or hemodialysis. Wynne et al. sought to determine whether a single injection of ghrelin could enhance food intake in patients with evidence of malnutrition receiving maintenance peritoneal dialysis [30]. Nine PD patients exhibiting mild to moderate malnutrition were subcutaneously administered either ghrelin or a saline placebo in a randomized, double-blind, cross-over protocol. Ghrelin administration significantly increased mean absolute energy intake during the study meals and non-significant increases in energy intake were observed over the first 24 h without a subsequent rebound. This research group subsequently sought to analyze the efficacy of repeated ghrelin administration in malnourished dialysis patients [87] by performing a double-blind randomized cross-over study of a week of daily subcutaneous ghrelin injections in a group of 12 malnourished dialysis patients. Ghrelin administration significantly increased appetite, with increases in energy intake noted at the first study meal. Persistence of this effect throughout the week was confirmed by food diaries and final study meals, indicating that daily ghrelin treatment resulted in a sustained positive change in energy balance in malnourished dialysis patients. In support of this data, experiments using a
nephrectomized rat model of renal cachexia demonstrated that daily treatment for two weeks with ghrelin or two GHS agents (BIM-28125 and BIM-28131) resulted in increased food intake, improved lean body mass accrual, and decreased circulating inflammatory cytokines [88]. Long-term studies are needed to demonstrate efficacy in improving appetite, weight gain, lean body mass, and quality of life.

3.2. GH deficiency-related disorders

Strong stimulation of GH secretion by ghrelin has been well documented in humans [12-16, 21, 42]. As with GHS, ghrelin may be useful for the diagnosis and treatment of short stature and GH deficiency. Elderly individuals may be particularly suitable candidates for ghrelin treatment, as ageing is associated with progressive decreases in GH secretion, appetite, and energy intake [89-92]. This reduced GH secretion is called “somatopause” and may be a cause of age-related metabolic and physiologic changes including reduced lean body mass and expansion of adipose mass. Sarcopenia is associated with functional decline and death. Altered blood lipid profiles also favor the development of vascular diseases that may increase overall mortality. The age-related reduction in energy intake has been termed “the anorexia of aging” and predisposes to the development of under-nutrition, which has been implicated in the
development and progression of chronic diseases commonly affecting the elderly, as well as in increasing mortality. Growth hormone therapy increases IGF-I levels, promotes anabolism, and increases muscle strength in healthy elderly individuals, as well as in selected patient groups [93-95]. Therefore, ghrelin and GHS may also have therapeutic potential to assist in the recovery of frail patients who require nutritional support and conventional rehabilitation [96]. We evaluated the effects of ghrelin administration on physical performance and body composition in patients undergoing elective total hip replacement (THR) as treatment for osteoarthritis (OA) in a randomized, double-blind, placebo-controlled, phase II study [31]. Thirty-two patients were assigned to two groups of 16 subjects each; the ghrelin group received intravenous injections of 2 μg/kg ghrelin twice daily for three weeks beginning one week before surgery, while the placebo group received vehicle alone. While ghrelin significantly increased lean body mass after the three-week injection period, it did not affect muscle strength or walking ability. Significant decreases in fat mass and GH responses to ghrelin injection were also observed. No severe adverse effects occurred in response to ghrelin treatment. Despite increased lean tissue reserves, ghrelin administration using this study protocol did not provide any favorable effect on physical performance in patients with OA undergoing THR. Further studies are necessary to examine the
efficacy of ghrelin treatment in such patients.

We found that plasma levels of acylated ghrelin in healthy elderly female subjects tended to be low and were correlated positively with IGF-1 levels, suggesting that negative feedback mechanism does not function properly in elderly subjects [97]. Further, acylated ghrelin concentrations in elderly females correlated with both systolic blood pressure and the frequency of bowel movements. These findings suggest that, in elderly females, acylated ghrelin may play a role in the regulation of the GH/IGF-1 axis, blood pressure, and bowel movements.

3.3. Post-gastrectomy and -esophagectomy

Body weight loss is common and is a serious outcome in patients who have undergone total gastrectomy and esophagectomy. Such weight loss correlates with decline in postoperative quality of life and is the most reliable indicator of malnutrition, which impairs immune function, susceptibility to infection, and survival [32, 33]. Plasma ghrelin levels decreased after total gastrectomy and esophagectomy [65, 98, 99]. Moreover, a significant correlation between ghrelin concentration and postoperative weight loss suggested a role for loss of ghrelin. To examine this, Adachi et al. evaluated the efficacy of ghrelin in 21 patients undergoing total gastrectomy [32]. Food intake and
appetite were significantly higher in the ghrelin group (3 μg/kg, twice daily for 10 days after starting oral food intake following surgery) compared with the placebo group, and BW loss was significantly lower in the ghrelin group than in the placebo group. Fat mass, lean body mass, and basal metabolic rate decreased significantly in the placebo group; however, the reductions in lean body mass and basal metabolic rate were not significant in the ghrelin group, although that of fat mass was significant. Thus, short-term administration of synthetic ghrelin successfully lessened postoperative body weight loss and improved appetite and food intake after total gastrectomy. Subsequently, the same research group performed a similar study in 20 patients who underwent esophagectomy [33]. Again, they found that administration of ghrelin after esophagectomy increased oral food intake and attenuated weight loss together with maintenance of lean body weight. Thus, ghrelin administration may be useful in minimizing the side effects of these operations.

3.4. Other disorders

Reflecting the wide expression patterns of both ghrelin and its receptor, this peptide is now known to play a role in a number of different physiological processes including cellular proliferation and differentiation, pancreatic exocrine and endocrine
function, glucose metabolism, sleep and behavior, immune regulation, and cardiovascular function. For example, as discussed above, repeated administration of ghrelin in patients with CHF significantly improved left ventricular function as well as food intake. A large number of studies have been performed by investigators worldwide to elucidate the various activities of ghrelin. We believe that some of these may lend support to the development of clinical applications of ghrelin to disorders other than those described above in the future.

4. Conclusions

More than ten years have passed since the discovery of ghrelin, and abundant evidence now indicates that it plays a role in a variety of physiological functions. In parallel, clinical trials have proceeded to exploit these activities in the treatment and diagnosis of human disease. There are several characteristic features of the clinical applications of ghrelin: 1) the multiplicity and uniqueness of its function, 2) its unique structure and fatty acid modification, and 3) the paucity of severe adverse effects [100]. These characteristics should allow us to develop novel and unique therapies for a variety of disorders, including many currently intractable and serious diseases. Indeed, research on clinical applications of ghrelin is a challenging and potentially rewarding
avenue for the future.
