Bulk metallic glasses (BMGs) are currently recognized as one of the most attractive fields of material science. They have been widely studied with great interest owing to their good mechanical, chemical, and magnetic properties. In order to overcome the major concern of the low ductility of BMGs, control of the nano structure as well as the alloy design has, usually, been applied. Recently, it has been found that the relaxation state of glassy alloys is also an important factor affecting the ductility. Kumar et al. have reported that the embrittlement of Zr-based BMGs can be reversed by substantially annealing for a short duration above the glass transition temperature, \( T_g \) (so-called recovery annealing). They investigated that the recovered ductility is correlated with the structural relaxation behavior in the glassy structure. The relaxation of BMGs annealed at low temperatures of around or below \( T_g \) has attracted great attention in terms of its effect on properties such as the local structure, thermodynamics, and crystallization. Very recently, the authors have reported the effect of the chamber atmosphere on the structure and properties of BMGs prepared by the Cu mold casting technique. We found the enhancement of the cooling effect when the alloy melt is cast in an Ar or He atmosphere rather than in vacuum, leading to the production of BMGs with various relaxation states by controlling the chamber atmosphere. Actually, we have produced less relaxed (unrelaxed) Zr-Al-Ni-Cu-Pd BMGs with improved compressive room-temperature ductility.

Thus, the structural relaxation of BMGs is recognized as one of the important phenomena with a considerable effect on their mechanical properties. Generally, we have to use BMGs with various relaxation states for industrial applications which originate from different production methods and conditions. However, little is known about the effect of the relaxation state on the fundamental kinetics of transformation behavior such as nucleation and grain growth in BMGs. In this letter, we investigate the change in the nucleation and grain growth rates of the primary quasicrystalline (QC) phase quantitatively in Zr\(_{65}\)Al\(_{7.5}\)Ni\(_{10}\)Cu\(_{12.5}\)Pd\(_{5}\) BMGs with different relaxation states. Such fundamental information will be useful for controlling the structure of BMGs through the precipitation of nano particles by annealing for the purpose of improving the mechanical properties.

Zr\(_{65}\)Al\(_{7.5}\)Ni\(_{10}\)Cu\(_{12.5}\)Pd\(_{5}\) bulk glassy samples with 3 mm diameter were produced by the Cu mold casting technique under various Ar and He pressures, in addition to a vacuum atmosphere. The cooling rate was monitored by a thin K-type thermocouple connected to an analog-to-digital converter. The relaxation state of the glassy structure was evaluated by the enthalpy of relaxation, calculated from the results of a specific heat measurement, with a heating rate of 0.33 K/s, under a purified Ar flow using a differential scanning calorimetry (DSC) (Perkin-Elmer Pyris Diamond DSC). The structure of the samples was analyzed by X-ray diffraction (Cu-K\(_{α}\), 40 kV-40 mA) and high-resolution transmission electron microscopic (TEM) observation (JEOL JEM 3000F). Glass transition (\( T_g \)) and crystallization (\( T_x \)) temperatures were determined by DSC measurements. The grain growth behavior of the annealed samples was directly observed using a TEM.

We have previously reported that the cooling rate of a supercooled liquid at low temperatures (\( ~T_g + 160 \) K) can be changed significantly by controlling the chamber atmosphere. Moreover, we proposed that the dominant factor determining the relaxed state in glassy alloys is the cooling rate at the above low temperatures, where each atom is fixed in its final position owing to the low mobility, resulting in a variety of relaxation states depending on the cooling rate. Figure 1(a) shows the relationship between the cooling rate just above \( T_g \) and the enthalpy of relaxation \( \Delta H_{\text{relax}} \) in the production of Zr\(_{65}\)Al\(_{7.5}\)Ni\(_{10}\)Cu\(_{12.5}\)Pd\(_{5}\) BMGs. \( \Delta H_{\text{relax}} \) can be obtained by the following equation:

\[ \Delta H_{\text{relax}} = C_1 T_g^{C_2} \]

\( C_1 = \text{constant} \)
\( C_2 = \text{constant} \)

This equation is used to estimate the enthalpy of relaxation for the production of Zr\(_{65}\)Al\(_{7.5}\)Ni\(_{10}\)Cu\(_{12.5}\)Pd\(_{5}\) BMGs.
The BMG shifts to a significantly less relaxed state with increasing cooling rate. The least relaxed state with \( \Delta H_{\text{relax}} = 0.79 \text{ kJ/mol} \) is achieved at a cooling rate of 1280 K/s in the present study. These BMGs with various relaxation states have similar XRD patterns, as shown in Fig. 1(b). The primary QC particles nucleate homogeneously and grow with an isotropic morphology. A phase transformation with an isotropic constant is expressed by the following equation, in terms of the isothermal annealing time \( t_a \):

\[
X = 1 - \exp\left( -\frac{\pi I_v a^3 t_a^4}{3} \right),
\]

(2)

where \( X \) is the volume fraction transformed, \( I_v \) and \( u \) are the homogeneous nucleation and grain growth rates, respectively. From Eq. (2), we can calculate the homogeneous nucleation rate \( I_v \) as follows:

\[
I_v = -\frac{3}{\pi a^3} \ln(1 - X).
\]

(3)

The change in \( u \), calculated from the maximum size of QC particles, with \( \Delta H_{\text{relax}} \) is revealed as the solid square (■) in Fig. 3(a). A strong correlation between the grain growth rate and the relaxation state is observed in the figure, in which \( u \) is markedly decreased with increasing \( \Delta H_{\text{relax}} \). The growth rates in the relaxed glasses at \( \Delta H_{\text{relax}} \approx 0 \) and 0.35 kJ/mol, for example, are \( 2.9 \times 10^{-9} \) and \( 2.3 \times 10^{-9} \) m/s, respectively, which are approximately twice as high as those in the less relaxed BMGs (1.8 \times 10^{-9} m/s at \( \Delta H_{\text{relax}} = 0.56 \text{ kJ/mol} \) and 1.2 \times 10^{-9} m/s at \( \Delta H_{\text{relax}} = 0.66 \text{ kJ/mol} \)). Since the macroscopic structure is almost the same for the relaxed and less relaxed BMGs, the difference of the grain growth rate might originate from the transition of the local structure at different cooling rates. This suggestion implies a change of the nucleation behavior of the primary QC phase with the relaxation state. \( I_v \) at 720 K in the steady state of \( X = 0.2 \), calculated from Eq. (3), is also plotted for the BMGs with various relaxation states as the solid circle (●) in Fig. 3(b). It is found that the calculated \( I_v \) has a significant correlation with the relaxation state, in which it increases with increasing \( \Delta H_{\text{relax}} \). \( I_v \) is \( 4.1 \times 10^{19} \text{ m}^{-3} \text{s}^{-1} \) in the almost fully relaxed sample (\( \Delta H_{\text{relax}} \approx 0 \)) and increases to \( 5.1 \times 10^{19} \text{ m}^{-3} \text{s}^{-1} \) at \( \Delta H_{\text{relax}} = 0.66 \text{ kJ/mol} \) and

\[
\Delta H_{\text{relax}} = 0 - 0.35 - 0.56 - 0.61 - 0.66 - 0.79 \text{ kJ/mol}
\]

at 720 K

FIG. 2. Bright-field TEM images of the primary QC particles in BMG samples with different relaxation states annealed at 720 K (\( \approx T_g \)) for various annealing times. The results for an almost fully relaxed state (\( \Delta H_{\text{relax}} \approx 0 \text{ kJ/mol} \)), in which the sample is annealed for a short time (approximately 60 s) just above \( T_g \), are also denoted in the figure.
1.1 \times 10^{20}/\text{m}^3 \text{ at } \Delta H_{\text{relax}} = 0.79 \text{ kJ/mol.} \text{ Actually, the observed TEM images in Fig. 2 indicate the precipitation of more QC particles with a smaller size in the less relaxed samples than in the relaxed samples. The tendency is in contrast to the relation between the grain growth rate and the relaxation state.}

The structural change in BMGs during relaxation has been studied by various methods.\textsuperscript{6,20,21} It was investigated that metallic glasses with a higher cooling rate have a smaller fraction of full icosahedra. During the relaxation process induced by annealing below \( T_g \), the fraction of full icosahedra increases. Additionally, it was pointed out that chemical ordering is enhanced in the relaxed state. Meanwhile, the growth mechanism of QCs in the glassy structure has also been investigated.\textsuperscript{22} Mechler et al. have reported that the formation of QC from the amorphous phase is determined by the rearrangement of the icosahedral clusters rather than by the attachment of single atoms.\textsuperscript{23} The results of molecular dynamics simulations have indicated that there is an increased presence of icosahedral clusters surrounding the QC nucleus. Furthermore, icosahedral clusters would like to “wet” the core of the QC nucleus owing to the reduction of interfacial tension.\textsuperscript{24} These clusters change the connectivity to ordered QC arrangements as the nucleus grows.

On the basis of these studies, BMGs prepared at a low cooling rate or in the relaxed state contain a limited number of ordered or grown QC nuclei, which might be equivalent to the chemical ordering discussed in Ref. 20. Consequently, it results in easy grain growth (i.e., a high growth rate) with a low nucleation rate. In contrast, considerably fewer ordered QC nuclei are present in less relaxed BMGs formed at a high cooling rate, preventing growth at these nucleation sites. In such a case, QCs have to grow from relatively disordered or an insufficient number of nuclei before the aggregation of related icosahedral clusters, which provide an opportunity for nucleation at many locally ordered regions (i.e., a high nucleation rate). This also results in difficult QC growth (a low growth rate) owing to the attachment of few clusters.

In the present study, we have found that the relaxation state strongly correlates to the nucleation and grain growth rates of the primary QC phase in \( Zr_{65}Al_{7.5}Ni_{10}Cu_{12.5}Pd_5 \) BMGs. The relaxed BMGs have lower nucleation rates and higher growth rates than the less relaxed BMGs. We suggest that this is due to the different state of the primary QC nucleus for a different relaxation state. A relaxed BMG has a considerably ordered or grown nucleus, which is formed by the aggregation of surrounding icosahedral clusters, leading to the easy growth from the limited number of sites. In contrast, nucleation frequently occurs from the other insufficient sites owing to the lack of such ordered or grown nuclei in less relaxed BMGs, resulting in high nucleation and low growth rates. Finally, the present results reveal the importance of controlling the relaxation state during the formation of nanostructures in BMGs and provide useful information for it.
