25 **Abstract:**

26 Isotope fractionation between the common Cu species present in solution (Cu^+ , Cu^{2+} ,
27 hydroxide, chloride, sulfide, carbonate, oxalate, and ascorbate) has been investigated
28 using both *ab initio* methods and experimental solvent extraction techniques. In order to
29 establish unambiguously the existence of equilibrium isotope fractionation (as opposed
30 to kinetic isotope fractionation), we first performed laboratory-scale liquid-liquid
31 distribution experiments. Upon exchange between HCl medium and a macrocyclic
32 complex, the $^{65}\text{Cu}/^{63}\text{Cu}$ ratio fractionated by -1.06 to -0.39% . The acidity dependence
33 of the fractionation was appropriately explained by ligand exchange reactions between
34 hydrated H_2O and Cl^- via intramolecular vibrations. The magnitude of the Cu isotope
35 fractionation among important Cu ligands was also estimated by *ab initio* methods. The
36 magnitude of the nuclear field shift effect to the Cu isotope fractionation represents only
37 $\sim 3\%$ of the mass-dependent fractionation. The theoretical estimation was expanded to
38 chlorides, hydroxides, sulfides, sulfates, and carbonates under different conditions of
39 pH. Copper isotope fractionation of up to 2% is expected for different forms of Cu
40 present in seawater and for different sediments (carbonates, hydroxides, and sulfides).
41 We found that Cu in dissolved carbonates and sulfates is isotopically much heavier
42 ($+0.6\%$) than free Cu. Isotope fractionation of Cu in hydroxide is minimal. The
43 relevance of these new results to the understanding of metabolic processes was also
44 discussed. Copper is an essential element used by a large number of proteins for
45 electron transfer. Further theoretical estimates of $\delta^{65}\text{Cu}$ in hydrated Cu(I) and Cu(II)
46 ions, Cu(II) ascorbates, and Cu(II) oxalate predict Cu isotope fractionation during the
47 breakdown of ascorbate into oxalate and account for the isotopically heavy Cu found in
48 animal kidneys.

1. INTRODUCTION

Copper has two stable isotopes, ^{63}Cu and ^{65}Cu , with respective average abundances of 69.174% and 30.826% in the reference metal SRM-NIST 976 (Shields et al., 1964). Variations of Cu isotope abundances in natural samples were identified by Walker et al. (1958) using thermal ionization mass spectrometry, but the variability of the mass bias at that time was too large with respect to the natural isotopic availability to qualify Cu isotopes as a potential geochemical or biochemical tracer. The advent of inductively-coupled plasma mass spectrometry (ICP-MS) instruments equipped with a magnetic sector and multiple collection made precise isotopic analysis of Cu possible (Albarède, 2004). Maréchal et al. (1999) published the first measurements of Cu isotope compositions in a variety of minerals and biological materials. The broad range of isotopic variations in Cu ores observed previously (Walker et al. 1958; Shields et al., 1965) was confirmed by subsequent work (Maréchal et al., 1999; Zhu et al., 2000; Albarède, 2004; Klein et al., 2009). Hereafter, the δ notation with

$$\delta^{65}\text{Cu} = \left(\frac{([^{65}\text{Cu}]/[^{63}\text{Cu}])_{\text{sample}}}{([^{65}\text{Cu}]/[^{63}\text{Cu}])_{\text{reference}}} - 1 \right) \times 1000 \quad (1)$$

is used throughout.

The narrow range of Cu isotope variation in basalts (Ben Othman et al., 2006; Archer and Vance, 2004; Herzog et al., 2009; Li et al., 2009; Moynier et al., 2010; Bishop et al., 2012) and granites (Li et al., 2009) suggests that high-temperature magmatic processes do not induce large Cu isotope fractionation. As a consequence, it makes Cu isotopes a tracer of choice for the study of sediments and more generally for

low-temperature processes such as those involved in soil formation (Bigalke et al., 2010, 2011) and in biology (Balter and Zarro, 2011; Weinstein et al., 2011).

Substantial isotope fractionation during chemical exchange reactions occurs at room temperature and reflects isotopic differences between the equilibrium constants of Cu isotopologues. Enrichment in ^{65}Cu of up to 0.8‰ was observed during the chromatographic elution of compounds (Matin et al., 1998; Maréchal et al., 1999, 2002; Zhu et al., 2002). The same technique demonstrates isotope fractionation of ~0.4‰ upon chromatographic separation of Cu(I) from Cu(II) (Matin et al., 1998; Zhu et al., 2002).

At low temperature, Cu isotopic abundances are also affected by inorganic surface processes (physical adsorption/desorption). Isotope separation of up to a few permil upon adsorption/desorption of Cu onto/from inorganic and organic substrates was observed by several groups (Mathur et al., 2005; Balistrieri et al., 2008; Pokrovsky et al., 2008; Navarette et al., 2011).

Copper plays very important roles in biology (Lippard and Berg, 1994). The metal centers of the ‘blue’ copper proteins are divided according to the coordination of the Cu ion into three types that contain one or more copper ions as prosthetic groups (Cowan, 1997). In plastocyanine, cysteine, histidine, and methionine ‘residues’ bind to Cu and this plays a major role for electron transfer (redox reactions) (Freeman and Guss, 2001). In humans, ceruloplasmin is a ferroxidase enzyme involved in the iron cycle, cytochrome c oxidase is involved in electron transfer across the membrane of mitochondrion, and superoxide dismutase protects cells against superoxide. Blue (Cu) proteins are ubiquitous and characterized by their multiple ways of bonding with amino acids. (Cowan, 1997). Coupling of Fe and Cu isotope fractionation has been identified

in human blood components (Albarède et al., 2011a) and in mammals (Balter and Zazzo, 2011; Albarede et al., 2011b). Depletion of $\delta^{65}\text{Cu}$ at the permil level was found in plants with respect to soils or nutrient solutions (Weinstein et al., 2011; Jouvin et al., 2012). $\delta^{65}\text{Cu}$ in enzymes is a few permil negative compared with the Cu isotopic composition of the host soil (Zhu et al., 2002). Positive $\delta^{65}\text{Cu}$ values up to 1.5‰ also were found in the kidneys of sheep (Balter and Zazzo, 2011) and mice (Albarede et al., 2011b).

Contrary to Fe (Hill et al., 2010; Rustad et al., 2010, and references therein), Ni (Fujii et al., 2011a), and Zn (Fujii et al., 2010, 2011b; Black et al., 2011; Pons et al., 2011; Fujii and Albarède, 2012), the theoretical prediction of Cu isotope fractionation among ligands (simple inorganic ligands like halide, sulfate, and phosphate ions, and more complex organic ligands as humic acids and phytoplankton exometabolites) in natural waters and biological fluids has only received minimal attention, which is a major hindrance for an informed interpretation of observations. This is the main motivation for the present work.

We first demonstrate that equilibrium isotope fractionation of Cu(II) does take place in laboratory-scale experiments. In parallel, we calculated the molecular orbitals of the corresponding Cu species to obtain the reduced partition function ratio (RPFR) of isotopologues. The *ab initio* calculations were then extended to hydrated Cu(II) complexes, hydroxide, sulfate, carbonate, ascorbate, and oxalate. The choice of ascorbate and oxalate was motivated by evidence of isotopically heavy Cu in the kidneys of sheep (Balter and Zazzo, 2011) and mice (Albarède et al., 2011b). Ascorbate is allegedly catabolized into oxalic acid (Chai et al., 2004; Massey et al., 2005; González et al., 2005), which makes some patients develop a condition known as hyperoxaluria and develop kidney stones, a calcium oxalate. The oxalate anions are

known to be strong complexing ligands of Cu(II) (Hayakawa et al., 1973), while ascorbate oxidase, which oxidizes ascorbate into dehydroascorbate (Solomon et al., 1996) is a bis(histidine)copper(II) compound. Applications of our calculations to the understanding of Cu isotope variability in marine sediments and to biological samples are briefly outlined.

2. METHODS

2.1. Extraction experiments and isotopic analyses

Dicyclohexano-18-crown-6 (DC18C6) (>97% purity) is a product of Fluka Chemie GmbH and Cu dichloride (hydrated, 99.9% purity) is a product of Wako Pure Chemical Industries, Ltd. Hydrochloric acid, in which the Cu impurity was certified to be less than 1.9 ppt, was purchased from Kanto Chemical, Co., Inc. Other chemicals were reagent grade.

CuCl₂·2H₂O was dissolved in HCl to prepare solutions of 0.1 mol dm⁻³ (M) Cu(II) in 1 to 6 M HCl. DC18C6 was dissolved in 1,2-dichloroethane to prepare a solution of 0.1 M DC18C6. Ten mL aqueous solution were combined with 15 mL organic solution in a glass vial, which was sealed. The two phases were stirred for 30 minutes using a Teflon-coated magnetic bar. After equilibrium was achieved, the two phases were separated by centrifugation at 2,000 rpm for 1 min, and an aliquot of the aqueous solution taken for analysis. A 10 mL aliquot of the organic solution was saved for back extraction of Cu in 15 mL of 0.02 M HCl. The extracted Cu was fully (>98%) recovered in this procedure. All these steps were carried out at 298 K. Copper concentrations in the equilibrated aqueous phase and the back extraction solution were determined by inductively-coupled plasma atomic-emission spectrometry (Thermo

Fisher Scientific, iCAP 6300 Duo). Aliquots of these solutions were saved for isotopic analysis.

Organic impurities carried over from the extraction step were separated from Cu on AGMP1 anion exchange resin in 7 M HCl as described in Maréchal et al. (1999). Copper isotopic compositions were measured on a Thermo-Finnigan Neptune MC-ICP-MS at Washington University in St. Louis. The samples were introduced by free aspiration in 0.1 M HNO₃ using a Teflon microcentric nebulizer (uptake rate of 100 µL/min) and a glass cyclonic spray chamber. Masses 63 and 65 were positioned on the L2 and axial collectors, respectively. Intensities of Zn isotopes (64, 66, 67 and 68) were measured on the collectors L1, H1, H2, H3, respectively. The intensity of ⁶²Ni was monitored in order to correct for the potential interference of ⁶⁴Ni. Instrumental mass fractionation was corrected by both Zn doping and standard-sample bracketing (Maréchal et al., 1999; Albarède, 2004). The typical external reproducibility of replicate analyses of the same samples carried out during different analytical sessions is 0.10‰ (2σ) for δ⁶⁵Cu.

2.2. Computational methods

Orbital geometries and vibrational frequencies of aqueous Cu(II) species were computed using the density functional theory (DFT) as implemented by the Gaussian09 code (Frisch et al., 2009; Dannington et al., 2009). The DFT method employed here is a hybrid density functional consisting of Becke's three-parameter non-local hybrid exchange potential (B3) (Becke, 1993) with Lee-Yang-and Parr (LYP) (Lee et al., 1988) non-local functionals. Using the 6-311+G(d,p) basis set or higher is recommended for calculating the Cu complexes by de Bruin et al. (1999). The 6-311+G(d,p) basis set,

169 which is an all-electron basis set, was therefore chosen for H, C, O, S, Cl, and Cu.
170 Molecules were modeled without any forced symmetry. An ‘ultrafine’ numerical
171 integration grid was used and the SCF (self-consistent field) convergence criterion was
172 set to 10^{-9} .

173 The isotope enrichment factor due to intramolecular vibrations can then be
174 evaluated from the reduced partition function ratio $(s/s')f$ (Bigeleisen and Mayer, 1947),
175 also noted β ,

$$\ln \frac{s}{s'} f = \sum [\ln b(u_i') - \ln b(u_i)] \quad (2)$$

176 where

$$\ln b(u_i) = -\ln u_i + \frac{u_i}{2} + \ln(1 - e^{-u_i}) \quad (3)$$

177 and

$$u_i = \frac{h\nu_i}{kT} \quad (4)$$

178

179 in which ν stands for vibrational frequency, s for the symmetry number of the Cu
180 compound, h the Planck constant, k the Boltzmann constant, and T the absolute
181 temperature. The subscript i denotes the i th mode of molecular vibration, and primed
182 variables refer to the light isotopologue. The isotope enrichment factor due to molecular
183 vibrations can be evaluated from the frequencies (ν) summed over all the different
184 modes. The isotopic difference in the stability constant of chemical reactions is identical
185 to the difference of $\ln \beta$ between related species. For example, a chemical exchange
186 reaction,

187

188 with stability constant K_{CuCl^+} , the isotope fractionation between the hydrated Cu^{2+} and

189 $CuCl^+$ is,

$$\ln \frac{K_{CuCl^+} (^{65}Cu)}{K_{CuCl^+} (^{63}Cu)} = \ln \frac{[^{65}CuCl^+]/[^{63}CuCl^+]}{[^{65}Cu^{2+}]/[^{63}Cu^{2+}]}$$

190

$$= \ln \beta_{CuCl^+} - \ln \beta_{Cu^{2+}} \quad (6)$$

191

192 Isotope fractionation also results from the mass-independent nuclear field shift
193 effect (Bigeleisen, 1996; Nomura et al., 1996, Fujii et al. 2009) which is an
194 isotope-dependent shift reflecting that the electronic orbitals do not vanish at the
195 nucleus and depends on the nuclear size and shape (King, 1984). The latest version of
196 quantum chemical models have taken finite-size nuclei into account in *ab initio*
197 calculations (Schauble, 2007; Abe et al., 2008, 2010; Fujii et al., 2010, 2011a,c,d). For
198 light elements such as Ni (Fujii et al., 2011a) and Zn (Fujii et al., 2010), the nuclear
199 field shift effect was found to be small as 0.02-0.03‰/amu. The isotope enrichment
200 factor via the nuclear field shift ($\ln K_{fs}$) is given by

201

$$\ln K_{fs} = \frac{hc}{kT} \nu_{fs} \quad (7)$$

202

203 where ν_{fs} is the nuclear field shift and c the velocity of light.

204 The contribution of the nuclear volume was estimated by the Dirac-Coulomb

205 Hartree-Fock (DCHF) method implemented in the UTChem program (see references in

206 Abe et al., 2008, 2010). We calculated the electronic structure of $\text{Cu}^0([\text{Ar}]3d^{10}4s^1)$,
207 $\text{Cu}^+([\text{Ar}]3d^{10})$, $\text{Cu}^{2+}([\text{Ar}]3d^9)$ and a few other simple Cu molecules. The Cartesian
208 coordinates of Cu molecules optimized by the Gaussian09 code were supplied to the
209 DCHF calculation. Exponents of basis sets were taken from Faegri's four-component
210 basis for Cu (Faegri, 2001), third-order Douglas-Kroll basis for H and Cl (Tsuchiya et
211 al., 2001), and ANO-RCC for O (Roos et al., 2005). Contraction coefficients were
212 optimized by four-component atomic calculations (Koc and Ishikawa, 1994). After
213 adding some diffuse and polarization functions, the final contraction form of the large
214 component basis sets was $(19s14p9d)/[6s4p3d]$ for Cu, $(16s11p1d)/[4s3p1d]$ for Cl,
215 $(14s9p2d)/[3s2p2d]$ for O, and $(8s2p)/[3s2p]$ for H.

216 The effect of nuclear spin can be neglected at equilibrium (Bigeleisen, 1996).
217 Since the present crown ether experiments were run at equilibrium, the kinetic part of
218 this effect also known as the magnetic isotope effect (Epov et al., 2011; Epov, 2011),
219 will not be considered in this work.

220

221 3. RESULTS AND DISCUSSION

222 3.1. Isotope fractionation of Cu by crown ether extraction

223 The Cu(II) species in HCl medium in the laboratory experiment are Cu^{2+} ,
224 CuCl^+ , CuCl_2 , and CuCl_3^- (Brugger et al., 2001), which are related through
225 complexation reaction 5 and the following stepwise reactions, with stability constants
226 K_{species} ,

227 and

228

229 The presence of CuCl_4^{2-} was reported for highly concentrated HCl and CuCl_2 systems
230 (Bell et al., 1973; Neilson, 1982; Tanimizu et al., 2007) or high-temperature systems
231 (Collings et al., 2000) but this higher order of complexation is negligible at the low HCl
232 concentrations and ambient temperature of the present experiments (Brugger et al.,
233 2001).

234 The extraction reaction of Cu(II) with the macrocyclic ligand can be written as,

235

236 where L stands for DC18C6. The distribution ratio D is written as,

$$D = \frac{\Sigma[\text{Cu(II)}]_{\text{org}}}{\Sigma[\text{Cu(II)}]_{\text{aq}}} \approx \frac{[\text{CuLCl}_2]}{[\text{Cu}^{2+}] + [\text{CuCl}^+] + [\text{CuCl}_2] + [\text{CuCl}_3^-]} \quad (11)$$

237

238 where the subscripts ‘org’ and ‘aq’ stand for the organic and aqueous phases,
239 respectively.

240 The isotope separation factor α , between the aqueous and organic phases, is
241 defined as:

$$\alpha = \frac{\sum_k \phi_{\text{org}}^k \left({}^{65}\text{Cu}/{}^{63}\text{Cu} \right)_{\text{org}}^k}{\sum_k \phi_{\text{aq}}^k \left({}^{65}\text{Cu}/{}^{63}\text{Cu} \right)_{\text{aq}}^k} \quad (12)$$

242

where k refers to the k th compound in the organic and aqueous phases, respectively, and ϕ is the fraction of total Cu (proper ^{63}Cu) hosted in the k th compound. The isotope enrichment factor is defined as $\alpha - 1$. Because α is always close to unity, $\alpha - 1 \approx \ln \alpha$, and $1000 \ln \alpha$ therefore can be approximated by $\Delta^{65}\text{Cu} = \delta^{65}\text{Cu}_{\text{org}} - \delta^{65}\text{Cu}_{\text{aq}}$. The $\Delta^{65}\text{Cu}$ values obtained are shown in Table 1 together with distribution ratios. $\Delta^{65}\text{Cu}$ ranged from -1.06 to -0.39‰ .

The yield of Cu(II) extraction by crown ethers has been investigated by Yoshio et al. (1980), Nakamura et al. (1982), and Contreras et al. (1993). A study on extraction kinetics showed that equilibrium is achieved within 30 sec (Nakamura et al., 1982). Hydration-dehydration is known to be the rate-limiting step of solvent extraction. The rate constant for H_2O substitution in the inner coordination sphere of Cu^{2+} is quite high in the transition metal series, and it is comparable with that of Li^+ of the alkali metals as observed by Eigen (1963). The isotope exchange rate kinetics of $^7\text{Li}/^6\text{Li}$ in the crown ether systems has been studied in detail (Jepson and Cairns, 1979; Nishizawa et al., 1984), in which the isotopic equilibrium is achieved within 30-60 sec after contacting aqueous and organic phases. The 30 min stirring period in the present study is therefore considered to be enough to achieve the isotopic equilibrium of Cu. The $\Delta^{65}\text{Cu}$ values listed in Table 1 are hence attributable to the equilibrium isotope effect.

Figure 1a shows the mole fractions of Cu species estimated by using the stability constants of reactions 5, 8, and 9 (Brugger et al., 2001). $\Delta^{65}\text{Cu}$ was found to vary with HCl molarity (Fig. 1b), a trend that reflects the isotope fractionation of Cu in reactions 5 and 8-10. With increasing HCl molarity, more CuCl_2 forms, which in turn results in an increase of D . The magnitude of $\Delta^{65}\text{Cu}$ shown in Table 1 is similar to that

found in other ligand exchange systems (Matin et al., 1998; Maréchal et al., 1999, 2002; Zhu et al., 2002).

3.2. Contribution of the mass-independent isotope effect

The total electronic energies calculated for Cu isotopes and isotopologues are shown in atomic units (a.u.) in Table 2, in which Cu^{2+} was chosen as the reference. The maximum effect was found to be 0.015‰ for the Cu^0 -Cu(I) pair and 0.012‰ for the Cu(I)-Cu(II) pair. The solvent extraction reaction is controlled by ligand exchange of Cu(II). Based on the Cu(II) data in Table 2, the nuclear field shift effect in Cu(II) species is only ~3% of the smallest $\Delta^{65}\text{Cu}$ value listed in Table 1. The values of $\Delta^{65}\text{Cu}$ reported in Table 1 are the values for the mass-dependent isotope fractionation and reflect intramolecular vibrations.

3.3. Mass-dependent isotope effects

3.3.1. Hydrated Cu(II) ions

The hydrated Cu(II) ion is generally represented as the hexaaqua complex $\text{Cu}(\text{H}_2\text{O})_6^{2+}$ (Fig. 2). It is known that $\text{Cu}(\text{H}_2\text{O})_6^{2+}$ shows the Jahn-Teller distortion effect (Sherman, 2001; Bersuker, 2006). Two Cu-O distances of the vertical axial bond (Cu-O_{ax}) are longer than four Cu-O distances in the equatorial plane (Cu-O_{eq}). The Jahn-Teller effect lowers the symmetry of $\text{Cu}(\text{H}_2\text{O})_6^{2+}$ from octahedral T_h to D_{2h} . The calculated bond distance of Cu-O and the literature values are shown in Table 3. The bond distances were calculated to be 2.02-2.03 Å (Cu-O_{eq}) and 2.30 Å (Cu-O_{ax}), which are consistent with those reported in the literature (see references in Table 3).

289 After evidence was found that the stable aqueous complex has a fivefold
290 coordination (Pasquarello et al., 2001), the Jahn-Teller effect of $\text{Cu}(\text{H}_2\text{O})_6^{2+}$ in aqueous
291 solutions has been questioned (Chaboy et al., 2006). The $\text{Cu}(\text{H}_2\text{O})_5^{2+}$ complex has five
292 identical Cu-O bonds with a length of 1.96 Å, which was identified by neutron
293 diffraction (ND) analysis combined with first-principles molecular dynamics (MD). The
294 common bond distance reflects the rapid switch between the square pyramid and
295 trigonal bipyramid configurations (Pasquarello et al., 2001; de Almeida et al., 2008). In
296 a Car-Parrinello MD simulation (Amira et al., 2005), a square pyramidal geometry with
297 four short (2.00 Å) and one long (2.45 Å) Cu-O bond could be optimized. A similar set
298 of bond distances, four short (1.97 Å) and one long (2.39 Å) Cu-O bond, has been
299 confirmed in an X-ray absorption study (Benfatto et al., 2002). Our calculation of the
300 $\text{Cu}(\text{H}_2\text{O})_5^{2+}$ geometry also resulted in the square pyramid rather than the trigonal
301 bipyramid of Fig. 2 and Table 4.

302 There is no clearly predominant structure among the four-, five-, and six- fold
303 coordinated Cu(II) ions (Chaboy et al., 2006). In the present study, we tested both the
304 coordination numbers five and six. We also tested a coordination number four to
305 evaluate the possibility of steric hindrance and strong degree of covalency. The
306 optimized structures in Cartesian coordinates are given in Table S1 of the electronic
307 supplement.

308 The intramolecular vibrational frequencies were then calculated for aqueous
309 Cu(II) species with optimized geometries. The $\ln \beta [= \ln (s/s')f]$ values for the isotope
310 pair $^{65}\text{Cu}/^{63}\text{Cu}$ were determined by employing Eqs. 2-4 and are listed in Table 5. The
311 value of $\ln \beta$ of $\text{Cu}(\text{H}_2\text{O})_5^{2+}$ at 298 K is 0.26‰ larger than that of $\text{Cu}(\text{H}_2\text{O})_6^{2+}$.

312

3.3.2. Hydrated Cu(II) chlorides

The structure of the hydrated Cu(II) chloride $\text{CuCl}_m(\text{H}_2\text{O})_n^{2-m}$ is shown in Tables 6 and S1 together with literature values. For the Cu(II) *monochloride*, CuCl^+ , both fivefold (D'Angelo et al., 1997) and sixfold (Rode and Islam, 1992; Texler et al., 1998) coordination have been reported. The bond distances obtained for the fivefold-coordinated $\text{CuCl}(\text{H}_2\text{O})_4^+$ reproduce the experimental results of D'Angelo et al. (1997). Though the geometry of sixfold-coordinated $\text{CuCl}(\text{H}_2\text{O})_5^+$ was optimized within the SCF convergence criterion, this species still showed a few imaginary (negative) frequencies. Tighter convergence criteria may be needed.

The Jahn-Teller effect should be detectable in the sixfold-coordinated Cu(II) *dichloride*, $\text{CuCl}_2(\text{H}_2\text{O})_4$. For a geometry with an axial Cl-Cu-Cl bond, we found two long and two short Cu-O bonds in the equatorial plane (Fig. 2). Our calculation agreed with the bond distances determined experimentally (Neilson, 1982; Tajiri and Wakita, 1986). A fivefold coordinated structure was inferred from the experiments of Ansell et al. (1995), and, indeed, we found evidence for a stable fivefold-coordinated $\text{CuCl}_2(\text{H}_2\text{O})_3$ structure with a distorted square pyramid (Fig. 2).

The X-ray diffraction study of Bell et al. (1973) reports the existence of sixfold-coordinated Cu(II) *trichloride*, $\text{CuCl}_3(\text{H}_2\text{O})_3^-$, which is an average structure of polymerized Cu(II) chlorides in a concentrated CuCl_2 solution. The complex has three Cu-Cl and three Cu-O bonds, a very low symmetry, and is unstable. The isolated CuCl_3^- anion in solution may have a different structure. There are no reports in the literature of the fivefold-coordinated $\text{CuCl}_3(\text{H}_2\text{O})_2^-$. Convergence could not be achieved for the square pyramidal nor the trigonal bipyramidal geometry. A smaller coordination number was found for hydrated CuCl_3^- (Collings et al., 2000). Under highly

concentrated HCl and CuCl_2 conditions, a higher order chlorinated CuCl_4^{2-} exists. It is disputed whether the structure is distorted octahedral $\text{CuCl}_4(\text{H}_2\text{O})_2^{2-}$ or tetrahedral CuCl_4^{2-} (see references in Table 6). Systematic analysis by the extended X-ray absorption fine structure (EXAFS) technique and Raman spectrometry suggested that a possible structure is the tetrahedral CuCl_4^{2-} (Tanimizu et al., 2007). This supports the existence of fourfold-coordinated $\text{CuCl}_3\text{H}_2\text{O}^-$. The calculation of $\text{CuCl}_3\text{H}_2\text{O}^-$ successfully converged.

The $\ln \beta$ values of the hydrated chlorides are shown in Fig. 3 and Table 5. As for the hydrated Cu^{2+} case, $\ln \beta$ (298 K) of the fivefold-coordinated $\text{CuCl}_2(\text{H}_2\text{O})_3$ was found to be 0.26‰ larger than that of the sixfold-coordinated $\text{CuCl}_2(\text{H}_2\text{O})_4$. A difference of this magnitude is assigned to a stereochemical effect. For the fivefold coordination, the $\ln \beta$ value at 298 K for $\text{Cu}(\text{H}_2\text{O})_5^{2+}$ is 0.56‰ larger than that of $\text{CuCl}_2(\text{H}_2\text{O})_3$ (Table 5). Likewise, for the sixfold coordination, the $\ln \beta$ value at 298 K for $\text{Cu}(\text{H}_2\text{O})_6^{2+}$ is also 0.56‰ larger than that of $\text{CuCl}_2(\text{H}_2\text{O})_4$ (Table 5). This suggests that, with the same coordination number, exchanging H_2O by Cl^- enhances $^{65}\text{Cu}/^{63}\text{Cu}$ fractionation by approximately the same amount.

As shown in Fig. 3, $\ln \beta$ decreases when the fraction of H_2O exchanged with Cl^- increases. The variation of $\Delta^{65}\text{Cu}$ estimated from the $\ln \beta$ values (298 K) with the molarity of HCl is shown in Fig. 1b. A similar observation was previously made for Ni and Zn isotope fractionation (Fujii et al., 2010, 2011a).

The isotopic mass balance is preserved in the extraction system as,

$$\frac{\Sigma [^{65}\text{Cu}]}{\Sigma [^{63}\text{Cu}]} = \frac{[^{65}\text{Cu}^{2+}] + [^{65}\text{CuCl}^+] + [^{65}\text{CuCl}_2] + [^{65}\text{CuCl}_3^-] + [^{65}\text{CuLCl}_2]}{[^{63}\text{Cu}^{2+}] + [^{63}\text{CuCl}^+] + [^{63}\text{CuCl}_2] + [^{63}\text{CuCl}_3^-] + [^{63}\text{CuLCl}_2]} \quad (13)$$

The mole fractions of related Cu(II) species are evaluated from the values of K_{CuCl^+} , K_{CuCl_2} , $K_{CuCl_3^-}$ (Brugger, 2001), and D (Eq. 11), all obtained experimentally. Each mole fraction is the sum of fractions of ^{63}Cu and ^{65}Cu isotopologues. The isotopic fractions within the species were estimated from $\ln \beta$. Since there is no structural information of the Cu-DC18C6 complex in organic solution, β_{CuLCl_2} was set as a free parameter. The results of the calculation are shown in Fig. 1b. The value of $\ln \beta_{CuLCl_2}$ converged to 3.35‰. The bold and dotted curves shown in Fig. 1b are the values of $\Delta^{65}\text{Cu}$ calculated for $\ln \beta_{CuLCl_2} = 3.35 \pm 0.05\text{‰}$. The results agree well with the experimental results. An important aspect of the estimation is that the calculation correctly predicts the sigmoidal dependence of $\ln \beta$ on the fraction of H_2O exchanged by Cl^- with increasing HCl molarity.

3.4. Application to hydrous geochemistry

In the absence of organic ligands which are known to dominate Cu speciation in seawater (Moffet, 1995; Moffet and Brand, 1996; Hirose, 2006) the free Cu^{2+} ion is dominant in freshwater, while the carbonate complexes CuCO_3 and $\text{Cu}(\text{CO}_3)_2^{2-}$ are dominant in seawater (Albarède, 2004). Copper concentration in seawater increase down the water column, which indicates both the uptake of Cu by plankton and scavenging of Cu by settling particles (Boyle et al., 1977; Bruland, 1980). Dissolved Cu in seawater is isotopically heavy ($\delta^{65}\text{Cu} = +0.9$ to $+1.5\text{‰}$) relative to rocks and sediments (0.0 to $+0.3\text{‰}$) and the riverine input ($+0.69\text{‰}$) (Bermin et al., 2006; Vance et al., 2008). It was suggested that this result is attributable to the partitioning of Cu

isotopes between a heavy dissolved phase, where Cu is bound to organic ligands, and a light particulate phase, dominated by Fe-Mn oxides (Vance et al., 2008). $\delta^{65}\text{Cu}$ in Fe-Mn nodules (Albarède, 2004) and encrustations (Little et al., 2010) from the three major ocean basins varies between +0.04 and +0.6‰, which is significantly lighter than the $\delta^{65}\text{Cu}$ value in seawater (+0.9 to +1.5‰, Vance et al., 2008).

Surface seawater also contains various inorganic complexes and carbonates. Speciation of Cu in seawater is very sensitive to the hydrolysis constants. Zirino and Yamamoto (1972) used the cumulative formation constant of $\text{Cu}(\text{OH})_2$, $\log \beta_2 = 14.3$, which, as shown in Fig. S1a (see the electronic supplement), makes Cu speciation in seawater dominated by $\text{Cu}(\text{OH})_2$. Mole fractions have been calculated from the set of stability constants recommended by Powell et al. (2007) with the second hydrolysis constant $\log \beta_2 = -16.65$, and the results are shown in Fig. 4a as a function of pH. At a typical seawater pH of 8.22 (Macleod et al., 1994), CuCO_3 is the dominant species, while the hydrated Cu^{2+} ion, chloride, sulfate, and hydroxide are subordinate. At $\text{pH} \geq 8.22$, $\text{Cu}(\text{CO}_3)_2^{2-}$ becomes an abundant species. These calculations are only relevant to seawater with no organic ligands.

Figure 4b shows the isotope fractionation of Cu(II) among its various species as estimated from their mole fractions and $\ln \beta$ (Tables 5 and 7) at 298 K under conditions typical of seawater. The optimized geometries of the relevant species are shown in Fig. 2 and Table S1 and the temperature dependence of $\ln \beta$ (Table 7) in Fig. 5. The geometry of Cu hydroxides, CuOH^+ and $\text{Cu}(\text{OH})_2$, were calculated by dissociating H^+ ions from the *fivefold*-coordinated $\text{Cu}(\text{H}_2\text{O})_5^{2+}$. The positions of OH^- ligands were determined by reference to CuCl^+ and CuCl_2 (Fig. 2). The structure calculated for both

$\text{CuOH}(\text{H}_2\text{O})_4^+$ and $\text{Cu}(\text{OH})_2(\text{H}_2\text{O})_3$ converged to a distorted square pyramid. With a H_2O molecule at the vertex of the square pyramid, the bond distance is shorter for $\text{Cu}-\text{OH}^-$ (1.8-1.9 Å) than for $\text{Cu}-\text{OH}_2$ (2.3-2.4 Å) (see Table S1). This suggests that the stronger Cu-O bonds on the square plane loosen the hydration bond from the vertex. This conclusion is consistent with the known structure of amorphous $\text{Cu}(\text{OH})_2$ or $\text{Cu}(\text{OH})_2$ colloidal solution, which both show a layer structure of polymerized square planes (Elizarova et al., 1999; Kriventsov et al., 1999).

Fourfold complexation occurs in both amorphous and crystalline $\text{Cu}(\text{OH})_2$. A stable fourfold complexation was also obtained for the Cu(II) carbonates, $\text{CuCO}_3(\text{H}_2\text{O})_2$ and $\text{Cu}(\text{CO}_3)_2^{2-}$ (Fig. 2 and Table S1). CO_3^{2-} was treated as a bidentate ligand. The structure converged to a distorted square plane. We tested positioning a water molecule above the plane in the initial structure, but it moved out of the inner coordination shell during the calculation. The structural optimization of CuCO_3OH^- was more problematic. Since CO_3^{2-} and OH^- occupy three coordination positions, one water molecule should also bind to Cu(II) at the fourth coordination position, thereby giving the $\text{CuCO}_3(\text{OH})\text{H}_2\text{O}^-$ compound. It was actually found that no water molecule is stable in the inner coordination shell. From the stoichiometry, the stable model molecule may instead be $\text{CuHCO}_3(\text{OH})_2^-$. This stable structure, in which HCO_3^- acts as a quasi-bidentate ligand is shown in Fig. 2 and Table S1. The $\ln \beta$ values obtained are shown in Fig. 5 and Table 7. The Cu hydroxides and carbonates have $\ln \beta$ values of 4.3-5.2‰ (298 K), in which compounds with higher complexation with OH^- and CO_3^{2-} resulted in $\ln \beta \geq 5\text{‰}$ (298 K).

The structure of hydrated Cu(II) in sulfate solutions was previously investigated by Ohtaki et al. (1976) and Musinu et al. (1983). In CuSO_4 solutions, Cu^{2+}

is surrounded by disordered ligands (Musinu et al., 1983), which suggests a direct interaction of Cu^{2+} with SO_4^{2-} . We used the structural model of Fe(III) sulfate proposed by Magini (1979) as a reference for $\text{CuSO}_4(\text{H}_2\text{O})_4$ (Fig. 2 and Table S1), in which SO_4^{2-} is treated as a monodentate ligand, and obtained bond distances of 1.9-2.1 Å for Cu-OH₂ and 2.37 Å for Cu-OSO₃²⁻. These values agree with the Cu-O bond distances determined by X-ray diffraction (Musinu et al., 1983). The electron donor SO_4^{2-} strongly attracts H⁺ and the resulting structure is equivalent to $\text{CuH}_2\text{SO}_4(\text{OH})_2$ (Fig. 2). The magnitude of $\ln \beta$ for CuSO_4 is 5.14‰ at 298 K (Table 7) and matches that of $\text{Cu}(\text{CO}_3)_2^{2-}$ (Fig. 5).

As shown in Figs. 4a and 4b, at pH ≥ 8.22, the dominant Cu(II) species are carbonates. We found that Cu in $\text{Cu}(\text{CO}_3)_2^{2-}$ (and CuSO_4) is isotopically 0.6‰ heavier than Cu^{2+} ion. At pH = 8.22, the $\delta^{65}\text{Cu}$ value of CuCO_3 is slightly negative -0.17‰, whereas those of $\text{Cu}(\text{CO}_3)_2^{2-}$ and CuCO_3OH^- are substantially heavier, 0.75‰ and 0.58‰, respectively. At high pH, the relevant fractionation factors are $\Delta^{65}\text{Cu}[\text{Cu}(\text{CO}_3)_2^{2-}-\text{CuCO}_3] = 0.92\text{‰}$ and $\Delta^{65}\text{Cu}[\text{CuCO}_3\text{OH}^- - \text{CuCO}_3] = 0.75\text{‰}$. Copper in carbonates, whether in CuCO_3 or in solid solutions with carbonates of other elements should therefore be isotopically light with respect to dissolved Cu.

At pH = 8.22, $\text{Cu}(\text{OH})_2$ is +0.48‰ heavier than bulk seawater Cu (Fig. 4b). A caveat is the somewhat different fractionation obtained when the cumulative formation constant of $\text{Cu}(\text{OH})_2$, $\log \beta_2 = 14.3$ of Zirino and Yamamoto (1972) is used. The major species are $\text{Cu}(\text{OH})_2$ and CuCO_3 , while mole fractions of other species are insignificant (Fig. S1a, Zirino and Yamamoto, 1972). The $\delta^{65}\text{Cu}$ shift of $\text{Cu}(\text{OH})_2$ and CuCO_3 at pH = 8.22 with respect to dissolved Cu are +0.02‰ and -0.62‰, respectively (Fig. S1b).

Isotope fractionation may therefore not be seen in Cu(II) hydroxide, but Cu in CuCO_3 should nevertheless remain isotopically light with respect to the seawater value.

As sulfides have small $\ln \beta$ values (Fujii et al., 2011b; Pons et al., 2011), sulfate-sulfide and carbonate-sulfide exchange are possibly determinant reactions for Cu isotope fractionation in seawater. $\text{CuHS}(\text{H}_2\text{O})_4^+$ and $\text{Cu}(\text{HS})_2(\text{H}_2\text{O})_3$ were calculated with the geometries shown in Table S1. The structures that successfully converged were similar to those of the hydroxides shown in Fig. 2. The $\ln \beta$ values are shown in Fig 5 and Table 7. It is clear that the $\ln \beta$ values of Cu(II) sulfides are smaller than those of all the species shown in Fig. 3. In particular, the $\ln \beta$ values of Cu sulfides are 1.9-2.0‰ smaller than those of Cu sulfate and carbonates. Diagenetic Cu(II)-bearing sulfides are expected to be isotopically lighter than dissolved Cu, while Cu in the water table of sulfide-rich terranes should be heavy (Mathur et al., 2005, 2012).

Isotope fractionation also occurs under reducing conditions through Cu(I)-Cu(II) redox reactions. The $\ln \beta$ values calculated for Cu(I) chlorides and hydrogensulfides are $\leq 2.6\text{‰}$ at 298 K (Seo et al., 2007), which suggests that Cu(I) complexes preferentially enrich ^{63}Cu and their precipitation results in the enrichment of ^{65}Cu in the fluid.

Cu in sulfides should be isotopically light with respect to dissolved aqueous Cu, and the main form of Cu removal from aquatic systems is Cu sulfide. The heavy isotopic composition of Cu in surface seawater (Vance et al., 2008) and groundwater (Mathur et al., 2012) therefore likely reflects that Cu carbonate complexes are held back in solution, while Cu is precipitated in sulfides. Complexation of Cu(II) with organic matter in surface seawater (Moffett, 1995) should also cause Cu isotope fractionation.

Evidence for the large-scale deposition of sediments with isotopically light Cu required by mass balance is, however, still missing.

3.5. Application to biological activity

A variety of biological processes may induce Cu isotope fractionation. Pokrovsky et al. (2008) demonstrated that Cu in bacteria is isotopically light relative to the ambient solution. Pokrovsky et al. (2012) further identified S-coordinated Cu(I) complexes at the surface and inside bacterial cells that may preferentially concentrate ^{63}Cu over ^{65}Cu . It is therefore appealing to assign isotope fractionation in biological material to competing Cu(II) and Cu(I) complexation. Mammal physiology is also a cause of Cu isotope fractionation. Albarede et al. (2011a) found a $\sim 1\text{‰}$ fractionation between human erythrocytes and serum. High $\delta^{65}\text{Cu}$ values of 1.5‰ were found in the kidney of both sheep (Balter and Zazzo, 2011) and mice (Albarède et al., 2011b) with respect to the rest of the body.

Oxalic acid is an ubiquitous toxic organic acid in body fluids. Oxalate is adsorbed in the intestinal track, but the question of the origin of high oxalate contents in urine and plasma found in patients prone to kidney damage is still contentious. This is a genuine medical concern as ascorbate (vitamin C) supplementation has been argued to increase the urinary oxalate levels, and therefore ascorbate may be a risk factor for individuals predisposed to kidney stones (Chai et al., 2005; González et al., 2005; Massey et al., 2005). Ascorbate is efficiently converted to oxalate when the coexisting copper concentration is high (Hayakawa et al., 1973).

Hayakawa et al. (1973) suggest that Cu(II) is readily reduced by ascorbic acid (H_2A) to Cu(I),

499

500 The ascorbate anion A^{2-} here is oxidized to A, dehydroascorbic acid $\text{C}_6\text{H}_6\text{O}_6$. In the
501 catalytic reaction by a multicopper oxidase, ascorbate oxidase, the oxidation of
502 ascorbate to dehydroascorbate occurs via the disproportionation of the
503 semidehydroascorbate radical (Solomon et al., 1996). The enzymatic reactions may be
504 identical to the catalytic reaction 14.

505 The monohydroascorbate anion HA^- forms a complex with Cu^{2+} , CuHA^+ .

506

507 Degradation of ascorbate via dehydroascorbate forms oxalate. A pathway of ascorbate
508 degradation has been proposed by Green and Fry (2005).

509 The oxalic acid also forms a complex with Cu^{2+} , CuC_2O_4 .

510

511 The value of the standard redox potential Eh with respect to the standard hydrogen
512 electrode (SHE), E_0 , for the Cu redox reaction,

513

514 is $E_0 = 0.153 + 0.591 \log ([\text{Cu}^{2+}]/[\text{Cu}^+])$ (Pourbaix, 1974). We used the following acid
515 dissociation constants and equilibrium constants $\text{p}K_{\text{a}} = 4.03$ (ascorbic acid), $\text{p}K_{\text{a}1} =$
516 1.252 , $\text{p}K_{\text{a}2} = 4.266$ (oxalic acid) (Smith and Martell, 1989), $\log K_{\text{CuHA}^+} = 2.32$

(Jameson et al., 1976), and $\log K_{\text{CuC}_2\text{O}_4} = 4.5$ (Foreci et al., 1995). Figure 6a shows the mole fractions of Cu^+ , Cu^{2+} , CuHA^+ , and CuC_2O_4 as functions of Eh. The total concentrations of Cu and ascorbic acid are $\sim 10^{-6}$ M (Lech and Sadlik, 2007) and $\sim 10^{-4}$ M (Margolls and Davis, 1988), respectively. The pH and Eh in the body are known to be ~ 7.4 and 0.27 V (van Rossum and Schamhart, 1991). These values were used to estimate the mole fractions of Cu species using the assumption that 10% of ascorbic acid is converted to oxalic acid. We further assumed that no other degradation products were present. Figure 6b shows the speciation as a function of the reaction progress. As expected, oxidation of Cu(I) to Cu(II) proceeds with increasing Eh, which in turn enhances Cu-ascorbate and Cu-oxalate formation. The degradation of ascorbate increases oxalic acid concentration and therefore promotes the production of Cu-oxalate.

Figure 6c and 6d show the range of isotope fractionation among Cu species as estimated from their mole fractions and $\ln \beta$ at 298 K (Tables 5 and 8). The optimized geometries of related species are shown in Table S1. Hydrated Cu^+ was treated as free Cu(I). Cu(I) complexes possess simple linear structures (Fulton et al., 2000a,b). Our $\ln \beta$ value of 2.87‰ at 289K for $\text{Cu}(\text{H}_2\text{O})_2^+$ (Table 8) is consistent with the value of 2.89‰ estimated by *ab initio* methods for CuClH_2O (Seo et al., 2007). $\text{Cu}(\text{H}_2\text{O})_5^{2+}$ was treated as free Cu(II), and its $\ln \beta$ is given in Table 5. For the geometry of Cu(II) ascorbate CuHA^+ , we used the copper monomer (Ünaleroğlu et al., 2001). The structure calculated for Cu(II) in fivefold coordination with L-ascorbate and H_2O is shown in Fig. 2 and Table S1. The value of $\ln \beta$ calculated at 298 K is 3.32‰. The $\ln \beta$ value of D-ascorbate at 298 K (also 3.38‰) is indistinguishable from that of L-ascorbate. The

geometry of Cu(II) oxalate was quite similar to the structure of the hydrated Cu carbonate. It successfully converged to a distorted plane configuration (Fig. 2 and Table S1) and led to large $\ln \beta$ values (Fig.7 and Table 8).

Figures 6c and 6d show the $\delta^{65}\text{Cu}$ values of the different species relative to the bulk solution as a function of Eh and extent of oxalate formation. Figure 6c shows that, with respect to free Cu(II), free Cu(I) is enriched in the light isotope. When Cu(I) and Cu(II) coexist, the $\delta^{65}\text{Cu}$ of the total free Cu ions is only slightly lighter than the sum of all the Cu species. The $\delta^{65}\text{Cu}$ of the Cu ascorbate varies from -1.0 to $+0.5\text{‰}$ when Eh increases from -1 V to $+1$ V, but its mole fraction remains very small. The prominent feature of Fig. 6c is the heavy isotope enrichment ($+0.6$ to $+2.5\text{‰}$) of the Cu oxalate relative to total Cu. Figure 6d was drawn for Eh = 0.27 V, which is a typical Eh value of human blood. It is expected that degradation of ascorbate and excretion of oxalate should leave isotopically heavy Cu in the kidney. With respect to food, which has a $\delta^{65}\text{Cu}$ value of about 0‰ (Balter and Zazzo, 2011), when even trace amounts of oxalate form, it should leave behind copper with a $\delta^{65}\text{Cu}$ of $\sim 1.4\text{‰}$. This value is very close to the $\delta^{65}\text{Cu}$ (of 1.5‰) found in sheep (Balter and Zazzo, 2011) and mice (Albarède et al., 2011b) kidneys. The positive $\delta^{65}\text{Cu}$ found in kidneys may result from isotopically heavy Cu left in the kidney by the degradation of ascorbic acid. Copper isotopes therefore represent a potential marker of the troubles associated with hyperoxalury and kidney stones.

4. CONCLUSIONS

We first demonstrated that Cu isotope fractionation at equilibrium is observed in laboratory-scale experiments. The effect on the $^{65}\text{Cu}/^{63}\text{Cu}$ ratio of Cu(II) partitioning between HCl and DC18C6 depends on acid molarity. The effect is mainly governed by the mass-dependent fractionations as a result of intramolecular vibrations. The nuclear field shift effect accounts for less than 3% of the mass-dependent fractionation. We then computed the coefficients of isotope fractionation of Cu for several species (hydrated Cu ion, hydroxide, chloride, sulfide, sulfate, carbonate, oxalate, and ascorbate). It was found that Cu in dissolved carbonates and sulfates is isotopically heavier than free Cu and Cu in sulfides. The theoretical estimation of $\delta^{65}\text{Cu}$ in ligand exchange between inorganic ligands including carbonate anions may be useful to understand the heavy Cu isotopic compositions found in both seawater and groundwater in the absence of strong organic ligands. Further theoretical estimation of $\delta^{65}\text{Cu}$ in hydrated Cu(I) and Cu(II) ions, Cu(II) ascorbates, and Cu(II) oxalate suggests that Cu isotope fractionation during the breakdown of ascorbate into oxalate results in the isotopically heavy Cu found in mammal kidneys.

ACKNOWLEDGMENT

The authors thank the anonymous reviewers and Associate Editor Mark Rehkämper for their useful suggestions and constructive comments on the manuscript. The authors wish to thank the generous help of Janne Blichert-Toft in editing the English of this paper. FM acknowledged the support of NASA EXO (NNX12AD88G) and of the Washington University I-CARES program.

3	2.4×10^{-2}	-0.77
4	1.5×10^{-1}	-0.65
5	4.6×10^{-1}	-0.61
6	9.8×10^{-1}	-0.39

970 ^a Errors are $\pm 0.10\text{‰}$ for 2σ .

971

Table 2 Nuclear field shift effect of Cu isotopes and isotopologues at 298 K.

Valence	Species	Total energy (a.u.)		ΔE (a.u.) (10^{-5})	Nuclear Field shift effect (‰)
		^{63}Cu	^{65}Cu		
Cu(0)	Cu^0	-1653.451898480	-1653.451827445	7.1035	-0.014
Cu(I)	Cu^+	-1653.210583752	-1653.210512731	7.1021	0.001
	CuCl	-2114.481787065	-2114.481716036	7.1029	-0.007
	CuH_2O^+	-1729.354508434	-1729.354437410	7.1024	-0.002
	CuOH	-1728.963440770	-1728.963369739	7.1031	-0.010
	Cu^{2+}	-1652.578696630	-1652.578625608	7.1022	0
Cu(II)	CuCl^+	-2114.155110496	-2114.155039471	7.1025	-0.003
	$\text{CuH}_2\text{O}^{2+}$	-1728.798913392	-1728.798842366	7.1026	-0.004
	CuOH^+	-1728.656622258	-1728.656551226	7.1032	-0.011
	CuO	-1728.336259331	-1728.336188299	7.1032	-0.011

^a The nuclear field shift effect was calculated by $(\delta E_{\text{reference}} - \delta E_{\text{species}})/kT$ at $T = 298\text{K}$. The root-mean-square charge radii $\langle r^2 \rangle^{1/2}$ reported for ^{63}Cu (3.8823×10^{-15} m) and ^{65}Cu (3.9022×10^{-15} m) (Angeli, 2004) were used. Cu^{2+} was set as the reference. Energy of photons of 1 a.u. is equal to 4.3597×10^{-18} J.

Figure captions

Figure 1 Mole fractions of Cu species and isotope fractionation of Cu in HCl

solutions. a) Distribution of Cu chlorides. The mole fractions were calculated from the stability constants of Brugger (2001). b) Isotope fractionation is shown as $\Delta^{65}\text{Cu} = \delta^{65}\text{Cu}_{\text{org}} - \delta^{65}\text{Cu}_{\text{aq}}$ upon extraction of Cu by dicyclohexano-18-crown-6 (DC18C6) from the aqueous solution. The solid curves represent our estimates from the $\ln \beta$ values (298 K) of fivefold-coordinated $\text{Cu}(\text{H}_2\text{O})_5^{2+}$, $\text{CuCl}(\text{H}_2\text{O})_4^{2+}$, and $\text{CuCl}_2(\text{H}_2\text{O})_3$, and $\text{CuCl}_3\text{H}_2\text{O}^-$ (Table 5), $\ln \beta_{\text{CuLCl}_2}$ (3.35‰), and D . The dotted curves represent the effect of $\pm 0.05\text{‰}$ errors on $\ln \beta_{\text{CuLCl}_2}$.

Figure 2. Molecular structures of hydrated Cu^+ , Cu^{2+} , and aqueous Cu(II) species.

The structures are drawn using GaussView5 (Gaussian Inc.) (Dannington et al., 2009). Symbol keys: Cu (vermilion), Cl (green), S (yellow), O (red), C (gray), and H (white).

Figure 3. Temperature dependence of $\ln \beta$. The $\ln \beta$ values of hydrated Cu^{2+} and Cu(II) chlorides (see Table 5) are shown as linear functions of T^2 .

Figure 4. Mole fractions of Cu(II) species and Cu isotopic variations as functions of

pH at 298 K. a) Mole fractions of Cu species, b) Species $\delta^{65}\text{Cu}$ relative to the bulk solution. Literature values of formation constants at ionic strength $I = 0.70$ M (Powell et al., 2007) were used for the calculations. $\Sigma[\text{Cu(II)}]$ was set to 10^{-9} M and it was assumed that the system was in equilibrium with air having a CO_2 fugacity of $10^{-3.5}$ bar (1 bar = 10^5 Pa) (Powell et al., 2007). We further assumed $\log K[\text{CO}_2(\text{g}) = \text{CO}_2(\text{aq})] = -1.5$ (Morel and Hering, 1993) and concentrations of $\text{Cl}^- = 0.55 \text{ mol kg}^{-1}$ and $\text{SO}_4^{2-} = 0.029 \text{ mol kg}^{-1}$ (Macleod et al., 1994).

Figure 5. Temperature dependence of $\ln \beta$. The $\ln \beta$ values of hydrated Cu(II) hydroxides, carbonates, sulfate, and sulfides (see Table 7) are shown as linear functions of T^2 .

Figure 6. Mole fractions of Cu(I) and Cu(II) species and Cu isotopic variations as functions of Eh and extent of oxalate formation at 298 K. pH and total Cu concentration were set to be 7.4 and 1 μM , respectively a) Mole fractions of Cu species as functions of Eh. Concentrations of ascorbate and oxalate were set to 90 μM and 10 μM , respectively. b) Mole fractions of Cu species as functions of proportion of oxalate formed. Eh was set to be 0.27 V. c) $\delta^{65}\text{Cu}$ relative to the bulk solution as functions of Eh. Conditions are identical to those of a, and d) $\delta^{65}\text{Cu}$ relative to the bulk solution as functions of extent of oxalate formation. Conditions are identical to those of b.

Figure 7. Temperature dependence of $\ln \beta$. The $\ln \beta$ values of hydrated Cu^+ and Cu(II) oxalate and ascorbate (see Table 8) are shown as linear functions of T^2 . The $\ln \beta$ values of pentaqua Cu^{2+} (see Table 5 and Fig. 3) are shown together.

Figure S1. Mole fractions of Cu(II) species and Cu isotopic variations as functions of pH at 298 K. a) Mole fractions of Cu species, b) Species $\delta^{65}\text{Cu}$ relative to the bulk solution. Conditions are the same with those of Fig. 4 except for second hydrolysis constant. $\log^*\beta_2 = -16.65$ used in Fig. 4 was substituted by $\log \beta_2 = 14.3$ and ion product $\text{p}K_{\text{W}} = 14$ (ionic strength $I = 0$).
