Introduction

The River Shinano is the longest river in Japan. Its location and the area
where the bottom sediments for this study were collected are shown in Figure 1.
Coastal subsidence and beach erosion around the estuary of the River Shinano
have been discussed recently. In 1958, more than 150 sediment samples, each
about 1.2-2 km apart, were collected in the area shaller than 65 m, using a
simple pipe dredge, by members of the Hydrographic Office of Japan. Grain-size
analyses of these samples were made by Mr. T. SATO (1960), who has the most
extensive data of sediment analyses around the Japanese coast. I have analyzed
136 samples (see Figure 2) for a quantitative analysis of the Foraminifera. The
river influence is clearly recognizable in the distribution of the Foraminifera and
grain size in these sediment samples.

Before going into a detailed description of the foraminiferal analysis, it should
be pointed out that there are many papers on brackish water foraminiferal
assemblages in bays, lagoons, sounds, estuaries, etc., but few on those in the open
ocean. Therefore, brackish water foraminiferal assemblages from the open ocean
are of interest both from the ecological and oceanographical point of view.

It gives me a great pleasure to dedicate this paper to Professor Francis P.
SHEPARD in thanks for the advice and help he gave me when attending the
Scripp’s Institution of Oceanography, La Jolla, California. I wish to express my
sincere thanks to Mr. Takahiro SATO of the Hydrographic Office of Japan, who
gave me these sediment samples for study of the Foraminifera and whose data
on their grain-size analysis have been of great use in my work; to Prof. Fred B

1) Presented at the Tenth Pacific Science Congress of the Pacific Science Association, held at the
University of Hawaii, Honolulu, Hawaii, U.S.A., 21 August to 6 September, 1961, and sponsored
by the National Academy of Sciences, Bernice Pauahi Bishop Museum, and the University
of Hawaii. An abbreviated form of this paper appeared in the “Shepard Commemorative

Phleger and Miss Frances L. Parker, Scripps Institution of Oceanography, University of California, for reading this manuscript; to Prof. Yoshiyuki Matsue, Fisheries Department, University of Tokyo, and Dr. Toshimasa Shimomura, Japan Sea Regional Fisheries Research Laboratory, who gave me advice on the

hydrographic information. Niigata Prefectural Fisheries Experimental Station furnished me with temperature and chlorinity data of sea water at Station F. Prof. Tomofusa MITSUHI of my institution and Prof. Takasi TOKIOKA, Seto Marine Biological Laboratory of Kyoto University have given constant encouragement to my study of Recent Foraminifera.

Figure 2. Locations of stations, at which sediment samples studied were taken.

Hydrography

The Foraminifera assemblages discussed here are not biocoenoses but thanatoconenes and for this reason there may be no direct relationship between these
assemblages and the hydrographic phenomena. However, the thanatocoenoses may well be related to the average oceanographic conditions pertaining during the past few hundred or thousand years. For this reason, I shall give a general picture of the oceanographic conditions in the area studied and that surrounding it.

It is well known that a coastal branch of the warm Tsushima Current flows along the coast of Honshu, on the Japan Sea side, in northeasterly direction, and that in the offshore region below the Tsushima Current (ca. 200-250 m in depth) there is the cold Liman Current which is, in turn, underlain by the characteristic water mass of the Japan Sea (Intermediate, Deep and Bottom waters). Only very few oceanographic data are available for the area concerned, since this area is a coastal region and is not important for fisheries or for meteorological observations. This area is covered by the Tsushima Current and, according to Shimomura and Miyata (1957, p. 32), the depth of the seasonal thermocline is 20 m off the River Shinano and 25 m off the Noto Peninsula. The surface water (shallower than 25 m, particularly above 10 m) of the Tsushima Current is influenced by river run-off and rain fall, but particularly in spring and summer

</table>

by the low saline water of the Eastern China Sea flowing into the Japan Sea through the Tsushima Channel. Thus, the chlorinity of the surface water is low and that of the water below 25 m level of the Tsushima Current is the highest. Some temperature and chlorinity data at eight stations A–H in this area are given below (Tables 1 A, B, 2 A, B) for reference. Stations A–G are shown on Figure 2-23.
1. The location of Station H is at 37°53.8' N. Lat., 138°50' E. Long. and it is about 23 km southwest of Station G. It is unfortunate that these 8 stations (A–H) are not influenced by the River Shinano. According to Dr. SHIMOMURA (personal communication, Nov. 1, 1961), the thickness of the fresh water-layer of the Shinano is ca. 3 m at the estuary and ca. 20–40 cm at points about 1–2 nautical miles from the estuary. The chlorosity of the water above and below the 3 m boundary is less than 2 g/L and more than 10 g/L respectively and there is no transitional zone between the two. The volume transport of the River Shinano is ca. 300–500 m³/sec.

Submarine Topography

The continental shelf off the coast of the northern part of Niigata Prefecture is very broad, being about 40–50 km wide. The depth of the shelf edge is about 150–160 m. The area surveyed in this study includes only the inner part of the shelf (see Figure 1). Contours were drawn at 5-meter intervals. These contours show that (1) the surface of the sea floor is smooth indicating that the area is presently depositional (i.e. is covered by Recent sediments; coarse sediments are known to be present farther offshore, indicating the presence of pre-modern sediments) and that (2) there is no subareal delta although there is a submarine delta-like feature at the mouth of the Shinano. The contours are about equally spaced in the northeastern part of the area, while the slope of the sea floor near the mouth of the River Shinano is steeper at the outer part. In the central part of the area, the slope of the floor is much steeper in the inner part than in the outer. This submarine topography is certainly due to the pouring of detrital sediments into the sea by the River Shinano and to the transportation of these sediments by the northeasterly flow of the Tsushima Current. The contours also show (3) that there is no influence on the submarine topography by the River Agano, though we can notice some influence by this river on the sediment grain size and Foraminifera distributions.

Grain-Size Distribution

Grain-size analyses of the sediments were made by Mr. T. SATO (1960). His results (Md₄ distribution) are given here (Figure 3) for reference. The distribution of the Md₄ contours of the sediments is very complicated off the mouth of the rivers Shinano and Agano, but is simple and nearly parallel to the shoreline in the northeastern part of the region where no strong river influence is recognized. Coarse sediments are distributed farther offshore near the mouth of the Shinano than they are off the rest of the area. It is apparent that the River Shinano has a great influence on the distribution of the sediment grain size and that the River Agano has the same influence, though to a lesser extent. SATO
Influence of River Shinano on Foraminifera and Sediment

(op. cit., p. 715, fig. 4) found a remarkable change in Mdφ value at depths of ca. 10 m and 35 m (Mdφ value being ca. 2.5 between 10 m and 35 m) and he considered the depth of 10 m to be the base of breaker action and the 35 m depth to be the so-called “wave-base” as well as the inner margin of the “mud belt”.

Figure 3. Distribution of grain size of sediments (Mdφ) (after T. SATO, 1960).

Foraminifera Distribution

Foraminifera assemblages mentioned here are thanatocoenoses but most of the foraminiferal tests have a fresh appearance, with the exception of a few specimens of Elphidium, Ammonia, Siphogenerina, etc. Therefore, any conclusions
obtained from this study may be modified when a detailed study of biocoenoses of Foraminifera are made in the future. It is believed that the major features of the distribution are essentially correct. A total of 102 species and varieties have been found in the area studied, of which only two are planktonic. Frequency distributions of major constituents of the benthonic species are shown in Table 3.

![Distribution of Buliminella elegantissima (D'Orbigny)](image)

Figure 4. Distribution of Buliminella elegantissima (D'Orbigny).

The planktonic species are Globigerina sp. (young form) and Globigerinoides ruber (D'Orbigny), their occurrences are scattered and extremely rare, and they are not listed in Table 3. By the same reason many benthonic species are not listed in Table 3. However, two very interesting species, Pseudobulimina simaensis (Makiyama & Nakagawa) and Asterigerinata sp. cf. A. pacifica Uchio, are
discussed later. It is to be noticed that seventeen species found in this area are also known from shallow marine sediments off the coast of Noboribetsu, southwestern Hokkaido, which is influenced by the cold Oyashio Current (Uchio, 1959, p. 300, Table 2). They are *Elphidium clavatum*, *Buliminella elegansima*, *Eggerella

![Figure 5. Distribution of Trochammina hadai Uchio, n. sp.](image)

— 227 —
Alveolophragmium crassimargo, Reophax scorpiurus, Asterigerinata cf. pacifica and Ammonia japonica. Of these, the presence of true cold water species as *Elphidium clavatum* is noteworthy. *Eggerella advena* and *Buliminella elegantissima* seem to prefer a cold shallow water environment, but they, particularly the latter species, are also reported from warm shallow water environment. *Elphidium clavatum* in this area may be a relict of the Pleistocene Period, but it is more probable to think that the area off the River Shinano is close to the southern limit of the distribution of *Elphidium clavatum* in Japan Sea. In the following paragraphs, the distribution of important species, rare but interesting species, benthonic populations and Foraminifera facies are discussed briefly.
Asterigerinata cf. pacifica Uchio occurs at Station 26 (depth 9.8 m) in very low frequency (0.1%). The species was reported (Uchio, 1959) at Stations 2 (65 m) and 11 (70 m) off Noboribetsu, Hokkaido (less than 1%).

Pseudobulimina simaensis (Makiyama & Nakagawa) occurs at Station 15 (42 m) in very low frequency (0.1%). The species was originally described from the Pleistocene formation of Mie-ken, and I find it from the Pleistocene formations of Aichi-, Kanagawa- and Chiba-ken, and the Pliocene Setana formation in Hokkaido. Occurrences of this species in Recent sediments are known so far from only two stations off Kinkazan (102, 349 m), where it is rare (Asano, 1959, p. 13).
Figure 4 shows the distribution of *Buliminella elegantissima* (d'Orbigny). This species is abundant in fine sand of shallow water (less than 10 m) but is not abundant in very coarse sediments. It seems to prefer a sea-water environment to a brackish-water environment.

![Distribution of *Buccella frigida*](image)

**Buccella frigida**

- > 10%
- < 10%
- < 5%
- < 1%

Figure 8. Distribution of *Buccella frigida* (Cushman).

Figure 5 shows the distribution of *Trochammina hadai* Uchio, n. sp. This species is most abundant (50-80%) off the Shinano and seems to be very sensitive to fresh water. It is reported as *Trochammina globigeriniformis* (Parker & Jones)
from some Japanese brackish waters (Hada, 1931, 1936, 1939, 1957; Maruhashi, 1948). Those who have studied the distribution of Recent Foraminifera may remember *T. inflata* (Montagu) which is also very characteristic of river-influenced areas in the United States and Europe. However, *T. hadai* can be easily distinguished from *T. inflata*.

![Diagram of Nonionella stella distribution](image)

**Figure 9.** Distribution of *Nonionella stella* Cushman & Moyer.

Figure 6 shows the distribution of *Trochammina* sp. cf. *T. pacifica* Cushman. This species seems to be distributed around the margin of the distribution of *T. hadai*, though there are some exceptions. Zalesny (1959, p. 109, text-fig. 8) finds that *T. pacifica* reaches its greatest abundance, making up 82% of the assemblage, at a point about two miles offshore in 17 fathoms of water, and the greatest
abundance of this species lies just beyond the end of the Hyperion sewage outfall at El Segundo. With increasing distance from this point in all directions, *T. pacifica* makes up less and less of the foraminiferal assemblages. *Zalesny*'s findings are in an area of open-ocean conditions in Santa Monica Bay, California.

Figure 10. Distribution of *Elphidium* spp.

His *T. pacifica* must be different from my *T. cf. T. pacifica* when considered from an ecological point of view.

Figure 7 shows the distribution of *Textularia earlandi Parker*. This species
is abundant throughout the area, which can be divided into two (northeastern and southwestern) parts by the frequency distributions of the species. The species seems to prefer a shallow, marine environment that is not strongly influenced by fresh water.

Figure 8 shows the distribution of *Bucella frigida* (Cushman). This species, like *Trochammina hadai*, seems to be very sensitive to fresh water. However, contrary to *Trochammina hadai*, this species seems to prefer a marine environment to a brackish water environment.

Figure 9 shows that the distribution of *Nonionella stella* Cushman & Moyer is rather similar to that of *Bucella frigida*. *Nonionella stella* seems to prefer a
shallow, marine environment that is not strongly influenced by fresh water.

Figure 10 shows that Elphidium (mostly *E. clavatum* Cushman) is abundant in the northeastern part of the area and also in the offshore area, and seems to prefer marine water to brackish water.

Figure 11 shows that the frequency distribution of *Siphogenerina raphanus* (Parker & Jones) is nearly parallel to the shoreline, though there seems to be a slight indication of the influence of the Shinano, and that this species becomes dominant toward offshore. This species seems to be a definitely marine species.

Figure 12 shows that the distribution of *Eggerella advena* (Cushman) is similar to that of *Siphogenerina raphanus*, though *Eggerella advena* has its high
frequency zone at depths between ca. 30 and 60 m and decreases further offshore. *Eggerella advena* seems to prefer a shallow, marine environment that is not strongly influenced by fresh water.

Figure 13 shows that the total benthonic population is clearly affected by

![Diagram](image)

**Figure 13.** Distribution of benthonic foraminiferal populations (number of specimens in 50 grams of dried sediment).

Md₆ distribution and, thus, by the River Shinano. Generally, the coarser the sediment, the smaller the Foraminifera population (compare Figure 13 with Figure 3).
Figure 14 shows the distribution of five Foraminifera assemblages. The *Trochammina* Assemblage clearly shows the influence of the Shinano. Each assemblage is briefly described in the following:

(1) *Ammonia* Assemblage—The assemblage is characterized by the occurrence
Influence of River Shinano on Foraminifera and Sediment

of high percentages of *Ammonia beccarii* (LINNÉ) var. *Buliminella elegantissima* is also very important and forms the highest percentages of the assemblage at five localities (see areas marked by an X in Figure 14). Other species found commonly in the assemblage are *Pseudorotalia japonica* *Asano*, *Textularia earlandi*, *Elphidium* spp., *Rosalina bradyi* (CURHMANN), *Reussella aculeata* CUSHMAN, etc. Less than ten species are found in this assemblage.

(2) *Trochammina* Assemblage—This assemblage is characterized by the highest frequency occurrences (usually more than 50%, maximum 88%) of *Trochammina hadai*. Other important species are *Textularia earlandi* and *Trochammina cf. T. pacifica*. Ten to thirteen species are found in this assemblage.

(3) *Textularia* Assemblage (I)—This is the inner *Textularia* assemblage and is characterized by the highest frequency occurrences (usually more than 50%, maximum 93%) of *Textularia earlandi*. Other important species are *Trochammina cf. T. pacifica*, *Elphidium* spp., *Siphogenerina raphanus*, *Buccella frigida*, *Ammonia japonica* (HADA), *Pseudorotalia gaimardii* (D'ORBIGNY), *Nonion manpukuijense* OTUKA, etc. Sometimes *Bolivina* cf. *B. robusta* BRADY, *Bulimina marginata* D'ORBIGNY, *Nonionella stella*, *Pseudononion japonicum* and *Loxostomoides karrerianum* (BRADY) are found. Ten to twenty species are found in this assemblage.

(4) *Elphidium* Assemblage—This assemblage is characterized by the highest frequency occurrences (20-50%) of *Elphidium* spp. (mostly *E. clavatum* CUSHMAN). *Textularia earlandi* is also abundant and usually forms higher percentages than *Elphidium* spp. This assemblage is distributed between the areas of the inner *Textularia* Assemblage (I) and the outer *Textularia* Assemblage (II), but is easily distinguished from them by high frequency occurrences of calcareous species, particularly *Elphidium* spp. and *Siphogenerina raphanus*, and by a greater number of species (20 to 35, average 25 species). Other important species are *Ammonia japonica*, *Pseudorotalia gaimardii*, *Nonionella stella*, *Buccella frigida*, *Trochammina cf. T. pacifica*, *Nonion cf. N. pacificum* CUSHMAN, *Epistominella tamana* (KuwANO), *Eggerella advena*, *Loxostomoides karrerianum*, etc.

(5) *Textularia* Assemblage (II)—This is the outer *Textularia* Assemblage and is characterized by the highest frequency occurrences of *Textularia earlandi*. Other important species are *Elphidium clavatum*, *Buccella frigida*, *Ammonia japonica* and *Siphogenerina raphanus*. Besides, *Trochammina cf. T. pacifica* and *Eggerella advena* are also common. Thirteen to seventeen species are found in this assemblage.

The distribution of the number of genera shows the same pattern as that of the number of species.

**Discussion**

As can be inferred from Figures 4-14, the distributions of species, assemblages and populations of Foraminifera are not directly influenced by the depth
of the bottom but by the River Shinano. Perhaps the physical characteristics (velocity, flow direction) of the river water and the amount of water, organic matter and detritus transported by the river are the most important factors for these peculiar distributions of Foraminifera. Temperature may be important for these distributions but the importance is obscured by the influence of the River Shinano. However, temperature influence may be recognizable in the north-eastern part of the area where the boundaries of the Foraminifera assemblages are generally parallel to the shoreline.

As mentioned above, the *Trochammina* Assemblage clearly shows the influence of the River Shinano. *T. hadai* constitutes 50-80% of the assemblage, and this species is widely distributed in Japanese brackish waters in abundance. Therefore, the *Trochammina* Assemblage may be due to the low salinity of the sea water caused by the River Shinano. However, the salinity of the bottom water in the area is as high as that of normal sea water, because the thickness of the freshwater layer from the River Shinano is about 3 m at the estuary and 20-40 cm at 1-2 nautical miles from the estuary and the river water does not touch the sea floor. Thus, salinity is not the main factor limiting the distribution of the *Trochammina* Assemblage. It appears that the same is true of the distribution of *Trochammina pacifica* in Santa Monica Bay (Zalesny, 1959). According to Hadä (1957, p. 48, 49), who has studied brackish-water Foraminifera of coastal lagoons and lakes of Japan, there are 15 species of Foraminifera that are adapted to brackish waters with salinities below 30%, of which two-thirds are arenaceous forms. Hadä believes that they consist of cosmopolitan and cold-water species. He believes that the water temperature is the most effective of the various environmental factors determining the distribution of Recent Foraminifera. I disagree that the brackish-water arenaceous Foraminifera are cold-water species and that their distributions are restricted chiefly by temperature. It seems to me that Hadä's idea is derived from the fact that brackish waters of very shallow lagoons and lakes in Japan (the depths from which Hadä's samples were taken are mostly less than a few meters, and some from about 10 m) are cooled during the winter and from the additional fact that many arenaceous Foraminifera are deep-sea inhabitants. If temperature is the limiting factor for the *Trochammina* Assemblage, why does this assemblage show the peculiar pattern that it does off the River Shinano and Santa Monica Bay regions? As above mentioned, there is no transitional zone between the fresh water of the Shinano and the underlying sea water. Therefore, the characteristics of the fresh water itself (temperature, salinity, etc.) have no influence on the benthonic Foraminifera. On the contrary, the detrital sediments and organic fragments carried by the River Shinano and deposited on the sea floor may influence on the benthonic Foraminifera distribution. When washing the present samples through a sieve (having openings of about 62 microns), I found a great deal of organic material. Generally organic material is considered to be an important food source of
Foraminifera. Particularly, *Trochammina pacifica* off Santa Monica and *Trochammina inflata* in many places are abundant around the sewage outfall, in coastal lagoons or bays and in marine marshes. In the area off the River Shinano there is no quantitative study of organic material contained in the sediments. However, it seems to me that the organic content is as high in the *Trochammina* Assemblage zone as in the other assemblage zones. Also, the distribution of the *Trochammina* Assemblage is not related to the grain size distribution (compare Figure 3 with Figures 5 or 14).

The fact that the lower boundary of the *Ammonia* Assemblage is about 10 m and that the assemblage is confined to the area of sand distribution suggests that the 10 m boundary may represent the base of strong turbulence caused by wave action.

**Conclusion**

The distributions of species, assemblages and populations of Foraminifera are affected by the River Shinano. A good example is the distribution of *Trochammina hadai*. Along a traverse directly off the mouth of the Shinano, the *Trochammina* Assemblage is distributed from nearshore to ca. 6 km offshore (ca. 55 m deep). The 6 km wide *Trochammina* Assemblage zone becomes narrower in a northeasterly direction and finally, in a wedge-shape pattern, disappears at a point ca. 15 km northeast of the river mouth at a depth of ca. 25 m. What factors of the river influence cause such a peculiar distribution of Foraminifera are not known. The detrital sediments and organic fragments transported by the River Shinano and deposited on the sea floor, salinity and temperature of the bottom water are not the most important factors, if considered separately, but may be very important synthetically.

The Foraminifera and grain-size distributions are influenced by the River Shinano to a remarkable extent. These distributions are similar in general pattern but differ in some respects. This is because the grain-size distribution of sediments is influenced mostly by physical processes of river and sea waters while the distribution of organisms, including Foraminifera, is influenced by physical, chemical, biological, geological and geographical factors. Therefore, the interpretation of the distribution of organisms is not easy but, when interpreted correctly, will give a better understanding of the environmental conditions of sediments than does the distribution of grain size. The significance of this cannot be overemphasized. Foraminifera assemblages in Recent marine sediments are very useful in interpreting fossil assemblages, and, thus, the depositional environment of sedimentary rocks (Some fossil Foraminifera assemblages found in the Tertiary formations of the Niigata, Yamagata and Akita oil fields are very similar to the Recent Foraminifera assemblages off the River Shinana). It is to be regretted that there is a tendency among geologists to rely only on the phy-
sical and/or chemical characteristics of sediments or sedimentary rocks. This appears to me be an erroneous and shortsighted view.

**Systematic Descriptions**

Four new species, two new subspecies and a species similar to a known species are figured in this area. In addition, *Haplophragmoides bradyi hokkaidoensis*, n. subsp., though not found in this area, is described here for the convenience of comparison with *H. bradyi niigataensis*, n. subsp. Brief taxonomic notes on some species are also mentioned. All specimens figured in this paper are deposited tentatively at my laboratory, Petroleum Engineering Institute, University of Tokyo. Some of the paratypes are deposited at the United States National Museum, Washington 25, D.C.

*Haplophragmoides bradyi hokkaidoensis* Uchío, n. subsp.

(Plate XVIII, Figures 7a, b)

Test free, small, compressed, nearly circular and lobulated in side view, planispiral, incompletely involute; periphery broadly rounded in edge view; chambers numerous, inflated, 6–6½, usually 6 chambers in the last whorl, those of the previous whorl slightly exposed in the depressed umbilical region; sutures distinct, depressed, straight, radiate; wall finely arenaceous with much cement, surface smooth and shining as polished, color reddish brown to yellowish brown; aperture interio-marginal, forming a crescentic slit at the base of the apertural face of the last chamber, with an upper lip.

Holotype (Uchío Collection No. TU-1001) from Station 10, off Noboribetsu, Hokkaido, Japan (N. Lat. 42°25'37", E. Long. 141°18'15"; depth 80 m). Length ca. 0.28 mm, width ca. 0.14 mm.

Remarks.···This new subspecies occurs at Station 6 (56 m), 3 (59 m) and 10 (80 m) in very low frequency (less than 1%) off Noboribetsu, Hokkaido (Uchío, 1959, p. 300, listed as *Haplophragmoides bradyi* in Table 2).

Comparison.···When I described *Haplophragmoides neobradyi* Uchío (1960, p. 51), I discussed the characteristics of *H. bradyi* (Robertson) in detail based on the original description and five topotypic specimens. *H. bradyi* is a nonvariable form, hence even a minor change in morphology becomes important in separating species or subspecies in *H. bradyi* group. *H. bradyi hokkaidoensis* differs from *H. bradyi* in having a less evolute, less deeply umbilicated test and fewer number of chambers in the last whorl. *H. bradyi hokkaidoensis* differs from *H. neobradyi* in having more chambers (*H. neobradyi* has 4–5 chambers) in the last whorl, and a slightly more inflated and more stout test.

—240—
Influence of River Shinano on Foraminifera and Sediment

Haplophragmoides bradyi niigataensis Uchio, n. subsp.

(Plate XVIII, Figures 6a, b)

Test free, small, subglobose, nearly completely involute in the young stages, slightly evolute and slightly umbilicate in the adult stages; periphery nearly circular and slightly lobulated in side view, very broadly rounded in edge view; five chambers in the last whorl, each gradually or slightly rapidly increasing in size as added; sutures distinct, depressed, straight or very slightly curved; wall finely arenaceous with much cement, surface smooth and shining as polished, color reddish to yellowish brown; aperture interio-marginal, forming a crescentic slit at the base of the apertural face of the last chamber, with an upper lip.

Holotype (Uchio Collection No. TU-1003) from Station 76, off the River Shinano, Niigata-ken, Japan (N. Lat. 18°3'3.2", E. Long. 138°9'28.3"; depth 65 m). Length ca. 0.33 mm, width ca. 0.27 mm.

Comparison...Haplophragmoides bradyi niigataensis differs from H. bradyi in having a much more inflated and less evolute test (H. bradyi always shows a part of the previous two whorls and hence is more deeply umbilicate). H. bradyi niigataensis differs from H. neobradyi in having a much more inflated test. H. bradyi niigataensis differs from H. bradyi hokkaidoensis in having a slightly less evolute and more inflated test, and fewer number of chambers in the last whorl.

The following table shows the characteristics of the various forms.

Textularia satoi Uchio, n. sp.

(Plate XVIII, Figures 1a, b; 2a, b)

Test free, small and fragile for the genus, tapering, broadest near the apertural end, elongate, about three times as long as broad, very strongly compressed, slightly inflated in the middle of the flattened sides, rarely slightly twisted; periphery somewhat acute, lobulate; chambers numerous, early ones close coiled at least in the microspheric form, later ones biserial, about twice as broad as high; sutures distinct, depressed, straight, oblique; wall arenaceous, composed mostly of fine sand grains and some relatively large ones; aperture a narrow slit.
at the base of the apartural face of the last chamber.

Holotype (Uchio Collection No. TU-1006) from Station 44, off the River Shinano, Niigata-ken, Japan (N. Lat. 38°4'43.8", E. Long. 139°12'55.8"; depth 60 m). Length ca. 0.27 mm; width ca. 0.12 mm.

Paratype (Uchio Collection No. TU-1006) from the same station as the holotype. Length ca. 0.27 mm; width ca. 0.11 mm.

Comparison. This new species can be easily distinguished from other species of the genus in having a small fragile and very strongly compressed test. *Tectularia antarctica* (Wiesner) (1931, p. 99, pl. 21, figs. 257, 258; pl. 23, fig. c) is close to this new species, but differs in having more inflated test, less elongate chamber, and aperture, a narrow slit, being parallel to the flattened side of the test instead of at right angles to them as in *T. satoi*.

**Elphidium clavatum** Cushman

I cannot compare my material with topotypic material of *Elphidium clavatum*. Cushman (1939) mentions the presence of this species in Recent sediments in Kiollie Fjord, Norway. I have a part of the Cushman's material in Killie Fjord (which Cushman gave it to Dr. Yoshiaki Ozawa), and find many specimens of this species. My specimens off the River Shinano and off Noboribetsu are identical to the Kiollie specimens as well as to the Arctic specimens figured by Loeblich & Tappan (1953). I have found many specimens of this species in a siltstone of the Wakimoto formation (Pliocene) at Oibanazaki, Wakimoto-mura, Minamiakita-gun, Akita-ken, Japan, which must be the same species as the one identified as *E. hughesi foraminosum* Cushman by Asano (1950). Asano's figures show that the sutures are straight (which means the specimen is identical to *E. foraminosum* (Cushman), but his description mentions the sutures are slightly curved toward periphery. My many specimens at Oibanazaki show curved sutures and should be identified to *E. clavatum*. *E. foraminosum* may be within the range of variation of *E. clavatum*.

—242—
Influence of River Shinano on Foraminifera and Sediment

Lagena pliocenica tokiokai Uchio, n. subsp.

(Plate XVIII, Figures 10a, b)

Test free, flask-shaped, the greatest width near the base which is truncated, with a long cylindrical neck, lower half of the test with many short raised longitudinal costae ending sometimes in acute projections near the base of the test; aperture at the end of an elongate, tapering neck ornamented with longitudinal costae, occasionally tending to become slightly spiral.

Holotype (Uchio Collection No. 1007) from Station 24, off the River Shinano, Niigata-ken, Japan (N. Lat. 38°4'50.3", E. Long. 139°17'33.1"; depth 39 m). Length ca. 0.58 mm, width ca. 0.28 mm.

Comparison.—This new subspecies differs from L. pliocenica in that the main portion of the test of L. pliocenica is roughly triangular or semi-circular in side view and thus the greatest width near the base, while that of L. pliocenica tokiokai is somewhat pyriform, and widest about the middle of it.

Trochammina hadai Uchio, n. sp.

(Plate XVIII, Figures 9a-c)

Test free, trochoid, finely arenaceous, dorsal side convex, ventral one usually flattened, umbilical area rather flat but deeply umbilicate in well preserved specimens, usually covered by fine particles, consisting of from 3 to 4 whorls, all visible from the dorsal side, only the last one from the ventral side; chambers inflated, somewhat subglobose, usually 5, occasionally 4 chambers in the last whorl, usually gradually, sometimes rapidly increasing in size as added; sutures slightly curved dorsally, more depressed and nearly radial ventrally; aperture an arched slit at the base of the apertural face of the last chamber; wall of sand grains and a variable amount of cement, outer surface fairly even, color reddish brown to yellowish brown.

Holotype (Uchio Collection No. TU-1009) from Station 70, off the River Shinano, Niigata-ken, Japan (N. Lat. 37°59'45.4", E. Long. 139°11'53.8"; depth 45 m). Length ca. 0.52 mm, width ca. 0.48 mm.

Remarks.—This new species seems to be widely distributed in Japanese brackish waters, and is reported as Trochammina (or rarely Ammoglobigerina) globigeriniformis (Parker & Jones) (Hada, 1931, 1936, 1939, 1957; Maruhasi, 1948, 1951; Takayanagi, 1955) or T. cf. globigeriniformis (Uchio, 1962 A, B). However, true T. globigeriniformis is a very common and widely distributed species in deep, cold waters (Cushman, 1910, p. 124; 1920, p. 78). I have many specimens of true T. globigeriniformis from San Diego Trough, California (Uchio, 1960, pl. 5, figs. 21, 22). T. hadai differs from T. globigeriniformis in having a
smaller and somewhat less stout test, less deeply depressed sutures, less inflated chambers, less lobulated periphery, and usually fewer number of chambers in the last whorl (though many specimens of *T. hadai* at Tanabe Bay have 4 chambers in the last whorl). Thus, the two species are distinct from each other in morphological as well as ecological characters. *T. hadai* also differs from *T. pacifica* CUSHMAN in having much more inflated chambers. The tribal name of this new species is dedicated to Mr. Yoshine *HADA* in recognition of his studies in the brackish-water Foraminifera in Japan.

**Trochammina** sp. cf. *T. pacifica* CUSHMAN

(Plate XVIII, Figures 8a–c)

Remarks... *Trochammina pacifica* CUSHMAN was originally described from off Virago Sound, off British Columbia at depths of 8–15 fathoms (CUSHMAN, 1925, p. 104). *T. charlottensis* CUSHMAN was described at the same time from the same area. I (UCHIO, 1960, p. 58) mentioned the difficulty of separating *T. pacifica* from *T. charlottensis*. I have many specimens of *T. pacifica* from off the San Diego, California, area (UCHIO, 1960, p. 59, pl. 3, figs. 26, 27), and have compared them with *T. cf. pacifica* off the River Shinano. It is found that the Japanese form is very close to the San Diego form, but has a more compressed and less deeply umbilicate test. Furthermore, each chamber of the San Diego form is more elongate than that of the Japanese form. As mentioned elsewhere in this paper, ZALESNY'S *T. pacifica* in Santa Monica Bay, California must be different from my *T. cf. pacifica* when considered from an ecological point of view. The Japanese form may be closer to *T. charlottensis* than to *T. pacifica*.

Hypotype (UCHIO Collection No. TU-1011) from Station 70, off the River Shinano, Niigata-ken, Japan (N. Lat. 37°59'45.4", E. Long. 139°11'53.8"; depth 24 m). Length ca. 0.48 mm, width ca. 0.39 mm.

**Bolivina hadai** UCHIO, n. sp.

(Plate XVIII, Figures 3a, b; 4a, b)

The free, somewhat compressed, slightly twisted, elongate, about three times as long as broad, broadest near the apertural end, tapering slightly toward the aboral end which always has a short spine; periphery lobulated in side view, rounded in edge view; chambers numerous, biserial, inflated, broader than high, increasing gradually in size as added except the last two which are relatively large; sutures distinct, slightly limbate, depressed except in early portions where they flush with surface, oblique, nearly straight; wall hyaline, somewhat coarsely perforate; aperture terminal, wide, elongate, curved, extending to the base of the
influence of the River Shinano on Foraminifera and Sediment

Holotype (Uchio Collection No. TU-1012) from Station 104, off the River Shinano, Niigata-ken, Japan (N. Lat. 38°9'53.5"; E. Long. 139°20'15.5"; depth 43 m). Length ca. 0.53 mm, width ca. 0.19 mm.

Paratype (Uchio Collection No. TU-1013) from Station 112, off the River Shinano, Niigata-ken, Japan (N. Lat. 38°11'58.4"; E. Long. 139°20'22.8"; depth 48 m). Length ca. 0.50 mm, width ca. 0.19 mm.

Comparison.—This new species is similar to Bolivina seminuda HADA (not Cushman) (HADA, 1931, p. 132, textfig. 89) in its general shape, apertural character and somewhat coarsely perforated wall, but differs in its slightly twisted test, much wider aperture, a short spine at the aboral end of the test, and its wall being somewhat coarsely perforated all over the surface in stead of being so only on the proximal area of each chamber as in B. seminuda HADA. This new species is also similar to B. tosaensis AsANO (1958, p. 23, pl. 4, figs. 3, 4) but differs in its much larger aperture, oblique and slightly limbate sutures and less coarsely perforated wall surface.

Bolivina tokiokai Uchio, n. sp.

(Plate XVIII, Figures 5a, b)

Test free, slightly compressed, elongate, about 2½ times as long as broad, periphery broadly rounded, tapering gradually, greatest breadth formed by the last two pairs of chambers, initial end bluntly pointed, without a spine, early portions slightly twisted; chambers numerous, biserial throughout, distinct except in early portions, somewhat inflated, broader than high, increasing gradually in size as added; sutures distinctly depressed, straight, horizontal except in early portions; wall coarsely pitted or finely reticulated except on the surface of the last chamber which is less so; aperture broadly elliptical, narrow at the base.

Holotype (Uchio Collection No. TU-1014) from Station 60, off the River Shinano, Niigata-ken, Japan (N. Lat. 38°3'55.1"; E. Long. 139°11'9.3"; depth 64 m). Length ca. 0.46 mm, width ca. 0.21 mm.

Comparison.—This new species is similar to Bolivina tosaensis Asano (1958, p. 23, pl. 4, figs. 3, 4), but differs from it in having more inflated test which has no spine at the initial end, aperture without a lip, and test tapering more gradually.
