(Received 22 April 2013; accepted 26 June 2013; published online 26 July 2013)

Adsorption of phenol and thiophenol (benzenethiol) on Cu(110) is investigated by a scanning tunneling microscope and electron energy loss spectroscopy. Phenol adsorbs intact and forms a cyclic trimer at 78 K. It is dehydrogenated to yield a phenoxy (C₆H₅O) group at 300 K. On the other hand, thiophenol is dehydrogenated to a thiophenoxy (C₆H₅S) group even at 78 K. Both products are bonded via chalcogen atom to the short-bridge site with the phenyl ring oriented nearly parallel to the surface. The C₆H₅O and C₆H₅S groups are preferentially assembled into the chains along the [001] and [112] directions, respectively. Dipole-dipole interaction is responsible for the chain growth, while the chain direction is ruled by the steric repulsion between chalcogen atoms and adjacent phenyl ring. This work demonstrates a crucial role of chalcogen atom of phenol species in their overlayer growth on the surface. © 2013 AIP Publishing LLC.

I. INTRODUCTION

Adsorption of aromatic molecules on solid surfaces has drawn much attention because the organic thin film has potential application in the field of surface engineering. It is essential to understand in detail the microscopic chemical bond and geometry at the interface of organic films and the substrates, which influence the macroscopic properties such as adhesiveness and mechanical resistance. Phenol has two functional groups, i.e., hydroxyl group and phenyl ring, which can be involved in the interaction with the surface as well as with the neighboring molecules. Therefore, it is important to understand their interplay for the rational functionalization of the interface. It is well established that phenol undergoes partial dehydrogenation to yield a phenoxy (C₆H₅O) group on various metal surfaces. By mainly using electron energy loss spectroscopy (EELS), Richardson and Hofmann showed that C₆H₅O is adsorbed on Cu(110) with its molecular plane nearly parallel to the surface, based on which the molecule was suggested to interact with the surface via both its aromatic ring and oxygen atom. However, the details of the binding structure, its temperature dependence, and the effect of intermolecular interaction remain yet to be clarified.

The adsorption of related sulfur-containing species on metal surfaces has also been studied from the viewpoint of surface functionalization with self-assembled monolayers (SAMs) anchored by stable metal-sulfur bonds. So far the study of thiol-based SAMs has been of considerable interest due to their technological applications in molecular electronic devices, chemical and biochemical sensors, and corrosion inhibitors. The benzenethiol (thiophenol) molecule, the simplest arenethiol, is analogous to phenol in that both the phenyl ring and the active anchor group (SH) can be involved in the interaction and reaction with the surface. Reflecting higher acidity of the SH group compared to the OH group for these compounds, thiophenol is dehydrogenated to thiophenoxy (C₆H₅S) species on metal surfaces at lower temperature. The molecular geometry of C₆H₅S on Cu(110) was suggested to be flat-lying in the same way as C₆H₅O. On other metal surfaces, however, it was suggested that the molecule stands up with the molecular plane tilted out of the surface plane, in contrast to the case of phenoxy group. Thus the functional groups (O and S) play a key role in optimizing the molecular structure, contributing to both the adsorbate-adsorbate and adsorbate-substrate interaction. A comparative study of phenoxy and thiophenoxy adsorption would unravel the different roles of S and O atoms in the interaction of these bi-functional molecules with the surface.

In this study we comparatively investigate phenol and thiophenol adsorption on Cu(110) by using a scanning tunneling microscope (STM) and EELS. Phenol adsorbs intact at 78 K and forms a cyclic trimer via H-bond interaction. It is partially dehydrogenated to yield C₆H₅O at 300 K, as reported in the literature. The local structure of C₆H₅O and C₆H₅S is qualitatively similar: they are bonded via chalcogen atom to the short-bridge site with the phenyl ring oriented nearly parallel to the surface. The dipole interaction between the molecules causes them to form one-dimensional chains along the [001] and [112] directions for C₆H₅O and C₆H₅S, respectively. It is proposed that the chain direction is ruled by the steric hindrance between chalcogen atom and phenyl ring of adjacent molecule.

II. EXPERIMENTAL

The experiments were carried out in an ultrahigh-vacuum chamber equipped with an STM operating at 4.5 K. Phenol, phenol-2,3,4,5,6-d₅ (C₆D₅OH), and thiophenol were obtained from Aldrich. The single crystalline Cu(110) surface was cleaned by repeated cycles of argon-ion sputtering and annealing. An electrochemically etched tungsten tip was used as an STM probe. The surface was exposed to the vapors at 78 or 300 K and subsequently cooled to 4.5 K for the STM measurement. The registry of the molecules to the surface
lattice was determined by their relative location with coadsorbed oxygen atom on the hollow site (Fig. S1 in the supplementary material). The adsorption states were characterized by electron energy loss spectroscopy (EELS, LK-5000, LK Technologies, Inc.). The primary electron energy 7 eV, incidence angle 60°, reflection angle 60° with respect to the surface normal, and typical energy resolution of 3 meV (the full width at half maximum of the elastic peak) were used. The surface was exposed to the vapors through a tube doser and subsequently probed by EELS at 110 or 300 K.

III. RESULTS AND DISCUSSION

A. Phenol adsorption

A typical STM image of Cu(110) exposed to phenol at 78 K is shown in Fig. 1(a). The image shows predominantly three protrusions in triangular shape, suggesting that the molecules form a cyclic trimer. As shown later, the EELS confirms that phenol adsorbs intact in a cyclic (closed) H-bond configuration. Cyclic phenol trimer also exists in free jets and solid phase. Due to the two-fold symmetry of the substrate, four equivalent configurations of trimer are observed (Fig. 1(b)). Two selected configurations are shown in Fig. 1(c), which are mirror images of each other against the reflection plane along [1 1 0] (dashed line). The chirality is created from the adsorption and clustering of achiral phenol molecules, as schematically shown in the bottom of Fig. 1(c). The orientation of H-bonds is clockwise or counterclockwise, although we cannot determine which image is ascribed to either configuration. As the exposure increases, the amount of trimer increases but larger clusters are hardly observed, indicating that phenol prefers cyclic (or closed) structure rather than extended chain.

When exposed at 300 K, the surface shows predominantly linear chains of protrusions along the [001] direction (Fig. 2(a)). Phenol is dehydrogenated to yield a phenoxy group (C₆H₅O) on Cu(110), as confirmed by the EELS (described later). Thus individual protrusions in Fig. 2(a) are ascribed to phenoxy groups.}

The EEL spectra for phenol adsorption on Cu(110) are shown in Fig. 3. The upper and lower spectra were recorded at 300 and 110 K, respectively. The 380 meV peaks are characteristic of sp² C–H stretch vibration mode, indicating that the phenyl ring remains intact upon adsorption on the surface at both temperatures. The lower-frequency peaks are assigned with the reference to the gas-phase counterpart, as summarized in Table I. The isotope substitution (C₆D₅OH) was employed to reinforce the assignment (Fig. S2 in the supplementary material). The O–H stretch mode is observed in the lower spectrum of Fig. 3 as a broad structure at ~400 meV.
FIG. 2. (a) A typical STM image of Cu(110) exposed to phenol at 300 K. The phenoxy groups form one-dimensional chains along the [001] direction. (b) STM images of an isolated phenoxy group taken at the same area. The molecule was manipulated by STM to change the orientation. The molecule appears to rotate around the short-bridge site (depicted by a dot) to which oxygen atom is bonded, as schematically shown in the bottom. (c) STM images of phenoxy chains. The molecules are arranged with a period of two-atomic distance (7.2 Å). They are oriented in either [001] or [00¯1] direction and in the same direction in each chain. The structures are depicted with van der Waals radii taken into account for each atom. The image size is 97×97 Å², 19×19 Å², and 24×36 Å² for (a), (b), and (c), respectively. The images were obtained at $V = 36$ mV and $I = 5$ nA.

~400 meV, indicating that the O–H bond remains intact at 110 K. We note that while the peak is not clear, it is intrinsic because the same feature is observed for the isotope spectrum in Fig. S2 in the supplementary material. The signature of the O–H bond is also observed at 173 meV, which is assigned as the O–H bending mode. The O–H stretch mode was observed at 450 and 400 meV for vapor (free) and solid-phase (cyclic) phenol, respectively. The H-bond interaction causes the elongation of the O–H bonds, giving rise to the decrease of the stretch mode frequency. The absence of the free mode (450 meV) indicates that phenol exists as a cyclic trimer on Cu(110). On the other hand, the O–H related modes are absent in the upper spectrum, indicating that phenol dissociates to a phenoxy group at 300 K. The appearance of the 29 meV peak assigned to O–Cu stretch is also consistent with the O–H cleavage and phenoxy formation. In both spectra, the peaks related to the phenyl ring are almost similar to those for gas-phase phenol, suggesting that the interaction of the phenyl ring with the surface is weak chemisorption, as in the case of benzene on the same surface. The dominant 93 meV peaks assigned to the C–H out-of-plane bend (wag) mode decrease in intensity in the off-specular direction (Fig. S3 in the supplementary material). The intense wag mode in the dipole-scattering regime is diagnostic for a phenyl ring parallel to the substrate; both phenol and phenoxy group are adsorbed in flat configuration, as depicted in Figs. 1(c) and 2(b), respectively.

B. Thiophenol adsorption

A typical STM image of Cu(110) exposed to thiophenol at 78 K is shown in Fig. 4(a). In contrast to the case of phenol, individual molecules are isolated and imaged as a protrusion accompanied with a tail. Similar images were observed for thiophenoxy groups (C₆H₅S) on Cu(111) and Au(111). The EELS shows no peak derived from S–H bond (~300 meV) at 110 K as well as at 300 K (upper). Therefore we assign individual STM images in Fig. 4(a) as thiophenoxy species and attribute the protrusion
FIG. 4. (a) A typical STM image of Cu(110) exposed to thiophenol at 78 K ($V = 50$ mV and $I = 5$ nA). Thiophenol is dehydrogenated to thiophenoxy ($C_6H_5S$) group which is oriented along either [1 ¯10] or [001] direction. (b) STM images of thiophenoxy groups in different orientations ($V = 50$ mV and $I = 1$ nA), and their schematic illustrations. Sulfur atom is adsorbed on the short-bridge site with the phenyl ring nearly parallel to the surface. The image size is $140 \times 140 \text{ Å}^2$ and $14 \times 14 \text{ Å}^2$ for (a) and (b), respectively.

and tail to the phenyl ring and sulfur atom, respectively. The peak assignment of EELS is conducted with reference to gas-phase thiophenol, as summarized in Table II. The intense C–H wag mode at $\sim 90$ meV again indicates the phenyl ring is nearly parallel to the surface. Figure 4(a) shows that isolated thiophenoxy groups are oriented along the [001] or [1 ¯10] direction. Out of 802 molecules imaged, 557 molecules were oriented along [001]; the former is favored by a factor of $\sim 3.8$. As shown later, the [001] species is thermodynamically stable while the [1 ¯10] species is metastable. The metastable [1 ¯10] species is observed because the conversion is kinetically limited at 78 K. Their close inspection and surface registry are shown in Fig. 4(b). The molecule can be manipulated by STM between the four configurations around the short-bridge site (shown by a dot in the top image of Fig. 4(b), suggesting that it is bonded via sulfur atom to the short-bridge site. We note that the local adsorption structure is similar between $C_6H_5O$ and $C_6H_5S$ groups, except that the [1 ¯10] orientation is additionally observed for the latter. At 300 K (Fig. 6), the thiophenoxy groups are predominantly oriented along [001]; the [1 ¯10] species turns into the [001] orientation by thermal activation, indicating that the [001] species is thermodynamically stable. It is notable that the $C_6H_5S$ groups are preferentially arranged along the [1 ¯12] or [ ¯112] direction, while the $C_6H_5O$ groups are predominantly arranged along the [001] direction (Fig. 2(a)). The difference in the chain direction implies the different role of chalcogen atoms in the chain assembly of the molecules.

C. Mechanism of chain formation

The phenoxy ($C_6H_5O$) groups are assembled into the chain along the [001] direction with the interval of two-atomic distance of Cu lattice (7.2 Å), as shown in Fig. 2(c). On the other hand, the thiophenoxy ($C_6H_5S$) groups favor the chain assembly along the [1 ¯12] or [ ¯112] direction (two-atomic distance along [001] and one-atomic distance along [1 ¯10], as shown in Fig. 6(b)). The schematic structures are depicted with the molecular dimensions assumed to be same as free $C_6H_5O(S)$ radicals and van der Waals radii for each atom. The molecules are oriented in the same direction in each chain, and thus, the electrostatic dipole-dipole interaction is most likely responsible for the preferential chain growth for both molecules. The inter-row coupling observed for thiophenoxy species in Fig. 6 also supports the dipole mechanism; the molecules in adjacent rows are always pointing in opposite directions, as shown in the inset. Electrostatic interaction between organic molecules plays a key role in one-dimensional and two-dimensional molecular assemblies on metal surfaces. Bartels and co-workers reported that thiophenoxy groups are assembled on Cu(111), in such a way that sulfur atom interacts preferentially with H atom in the ortho position of adjacent molecule. This selective C–H···S interaction (a kind of hydrogen bond) was argued in term of charge density difference between the positions of H atom. For the assembly on Cu(110), no preference of ortho position is observed as shown in Fig. 6(b), indicating that the mechanism of interaction and assembly pattern critically

![EEL spectra recorded for $C_6H_5SH$ at $300 \text{ K}$ (top) and $110 \text{ K}$ (bottom). Either spectrum shows no S–H stretch peak at $\sim 300$ meV, indicating that thiophenol is dehydrogenated to thiophenoxy species even at $110 \text{ K}$. The peak assignment is summarized in Table II.](image-url)
are propelled into the chain by complementary dipole-dipole interaction.

Then what causes the difference in the chain direction between C₆H₅O and C₆H₅S groups? The chain structures depicted in the bottom of Figs. 2 and 6 for C₆H₅O and C₆H₅S groups, respectively, with their van der Waals radii taken into account, illustrate how the chain direction is ruled by chalcogen atoms: C₆H₅S groups are arranged along the [112] or [112] direction so that they maximize the benefit from the dipole interaction while avoiding the steric hindrance between sulfur atom and the adjacent phenyl ring. Thus the chain direction is qualitatively explained in terms of the difference of the van der Waals radii between oxygen and sulfur atoms.

IV. SUMMARY

The adsorption and molecular interaction of phenol and thiophenol molecules on Cu(110) are studied by STM and EELS. Phenol adsorbs intact while thiophenol leaves S–H hydrogen to yield a thiophenoxy (C₆H₅S) group at 78 K. The former is dehydogenated to yield a phenoxy (C₆H₅O) group at 300 K. Both phenoxy and thiophenoxy species show similar local structures; they are bonded via chalcogen atoms to the short-bridge site with the phenyl ring oriented nearly parallel to the surface. On the other hand, they prefer chain growth along different directions, which is ruled by the interplay between attractive dipole-dipole interaction and the steric repulsion between chalcogen atoms and phenyl ring.
