Preface

Interferon (IFN)- γ , a cytokine with antiviral, immunomodulatory, and antiproliferative activities, has been extensively studied as a treatment for many diseases, such as viral infections, allergic diseases and cancer. However, a major limitation of IFN- γ -based therapy is the short *in vivo* half-life of IFN- γ . Therefore, IFN- γ gene transfer has been considered to be a promising method to overcome this limitation because, theoretically, it should be able to extend the duration of action of the short-lived cytokine.

Previous studies in my laboratory showed that the removal of unmethylated cytosine-phosphate-guanine (CpG) dinucleotides from plasmid DNA prolonged the plasmid-mediated transgene expression. A single injection of pCpG-Mu γ , a CpG depleted plasmid DNA encoding murine IFN- γ , via tail vein using hydrodynamic injection method resulted in prolonged therapeutic serum concentrations of IFN- γ over 1 month. This sustained transgene expression of IFN- γ could be used as a new therapeutic strategy for chronic diseases, but no such attempts have been made thus far. Therefore, in this thesis, I aimed to investigate the beneficial effects of sustained exogenous expression of IFN- γ in treating atopic dermatitis and cancer in mouse models.

In Chapter I, NC/Nga mice, a model of human atopic dermatitis, at two different stages of the disease were used. In Section 1, NC/Nga mice without dermatitis, which represent ones at a stage before the onset of the disease, were used to study the effects of IFN- γ gene transfer in preventing atopic dermatitis. The mice were injected with pCpG-Mu γ or pCMV-Mu γ , a conventional short-term IFN- γ -expressing plasmid, into the tail vein using hydrodynamic injection method to, first, examine the importance of the duration of action of IFN- γ in regulating the balance of T helper (Th) cell subsets (Th1 and Th2) in NC/Nga mice. Then, it was examined whether the sustained supply of IFN- γ is necessary for preventing the onset of the disease development. In Section 2, NC/Nga mice with early phase of dermatitis were used to investigate whether the sustained IFN- γ expression is effective in ameliorating or treating the symptoms of the disease.

In Chapter II, the beneficial effect of sustained expression of IFN- γ in treating cancer was investigated. Because it was found that IFN- γ gene transfer also induces the expression of indoleamine 2,3-dioxygenase 1 (IDO1), a tryptophan-metabolizing enzyme involved in the induction of tumor immune tolerance in a variety of organs of mice. Therefore, the Lewis lung carcinoma (LLC) tumor-bearing wild-type and IDO1 knockout mice were used to investigate whether IFN- γ gene transfer-mediated IDO1 upregulation counteracts the anti-tumor activity of IFN- γ .

Chapter I

Improvement of atopic dermatitis by sustained exogenous expression of IFN- γ in NC/Nga mice via Th1 polarization

Section 1

Sustained expression of IFN- γ ameliorates the development of atopic dermatitis

I-1-1 Introduction

The number of patients with allergies, including those with asthma, pollinosis, and atopic dermatitis, has been increasing in recent decades, especially in developed countries. Atopic dermatitis, one of the most common allergic diseases, is a chronic inflammatory skin disorder accompanied by particular skin lesions. The main characteristics of atopic dermatitis are eczematous skin lesions, epidermal hypertrophy, intense pruritus and infiltration by inflammatory cells. Increased serum immunoglobulin (Ig) E and an excessive production of T helper (Th) 2 cytokines are also frequently observed in patients with atopic dermatitis. It is believed that this disorder is associated with the imbalance of Th lymphocyte subpopulations (Th1 and Th2), which play major roles in the immune response [1]. Under normal conditions, the differentiation of naive T cells to Th1 and Th2 lineages is regulated by cytokines that are secreted from various cells, including themselves, and the Th1/Th2 balance is maintained. However, in atopic dermatitis, the balance shifts to Th2 dominance. This eventually leads to excessive Th2 cytokine production. Th2-like immune responses play an important role in the pathogenic mechanism of atopic disorders, because Th2 cytokines mediate excessive IgE production, a major cause of atopic inflammation [2-5].

Nishiki-nezumi Cinnamon/Nagoya (NC/Nga) mice are a mouse model of human atopic dermatitis. These mice spontaneously develop atopic dermatitis-like skin lesions around the age of 6 to 8 weeks when raised under conventional housing conditions but not under specific pathogen-free conditions. The skin lesions of conventional NC/Nga mice are characterized by erythema, hemorrhage, edema, erosion, scaling and dryness of the skin. Hyperproduction of IgE and Th2-type chemokines have also been reported in these mice. These clinical features are similar to those of human atopic dermatitis [4, 6-8].

IFN- γ , a Th1 cytokine, inhibits the differentiation of naive T cells to Th2 cells, as well as the production of Th2 cytokines from Th2 cells. Thus, IFN- γ has been considered to be capable of correcting the Th1/Th2 imbalance and is effective in the treatment of diseases in which the balance is impaired, such as atopic dermatitis [9]. Despite such positive features, few attempts have been made to use IFN- γ as a pharmaceutical agent for the treatment of atopic dermatitis [10-13]. This is mainly due to the fact that IFN- γ , as well as other IFNs, has a short *in vivo* half-life, and multiple injections are required to maintain its concentration at levels high enough to prevent dermatitis [14].

Several approaches have been developed to extend the duration of the therapeutic effects of biologically active proteins. Extension of the *in vivo* half-life of proteins can be achieved by using controlled- or sustained release systems [15-18] or by chemical modification of proteins [19-21]. Pepinsky et al. [22] demonstrated that the high clearance of IFN- β -1a was reduced by PEGylation, and its increased systemic exposure resulted in better antiviral effects. PEGylated IFN- α in combination with an antiviral drug, ribavirin, is now a standard treatment for hepatitis C virus-induced chronic hepatitis. The increased half-life of IFNs obtained by PEGylation has greatly increased their therapeutic efficacy. In addition to these challenges, gene delivery is an option to increase the *in vivo* half-life of therapeutic proteins, including IFNs. Previous studies in my laboratory demonstrated that the depletion of CpG motifs in plasmid vectors is an effective approach for extending the duration of transgene expression [23, 24]. Additionally, a murine IFN- γ -expressing

plasmid DNA, pCpG-Mu γ , which contains no CpG motifs except for those in the cDNA region was also developed [25]. A single hydrodynamic injection of pCpG-Mu γ resulted in a high and sustained IFN- γ concentration in the serum over 1 month in healthy ICR mice. However, little is known about how such a sustained transgene expression of IFN- γ influences the Th1/Th2 balance under Th2-dominant conditions.

In this section, I injected pCpG-Mu γ into a human atopic dermatitis model (NC/Nga mice), to achieve a sustained transgene expression of IFN- γ . A conventional CpG-replete plasmid vector expressing IFN- γ , pCMV-Mu γ [24, 26], was also used for comparison to examine the importance of the duration of transgene expression on the immunological changes induced by IFN- γ gene transfer. The expression profile of IFN- γ was first examined in NC/Nga mice, and the effect of the expression on the level of interleukin (IL)-4, -5, -10, -12, -13, -17, and thymus and activation-regulated chemokine (TARC) was evaluated. Then, skin lesions, the intensity of scratching behavior, transepidermal water loss (TEWL), the thickness of the epidermis, and the infiltration of the skin by inflammatory cells were evaluated.

I-1-2 Materials and Methods

Animals

Five-week-old male C57BL/6 mice and 6-week-old male NC/Nga mice that were raised under conventional conditions, but had not developed dermatitis, were purchased from Japan SLC (Hamamatsu, Japan) and maintained on a standard food-and-water diet under conventional housing conditions. The protocol for the animal experiments was approved by the Animal Experimentation Committee of the Graduate School of Pharmaceutical Sciences, Kyoto University.

Plasmid DNA

Two types of IFN- γ -expressing plasmid vectors developed in my laboratory were used: pCMV-Mu γ , which was constructed by inserting a murine IFN- γ cDNA fragment into the BamHI site of pcDNA3 (Invitrogen, Carlsbad, CA) [26], and pCpG-Mu γ , which was constructed by inserting the BglII/NheI IFN- γ cDNA fragment amplified by PCR from the pCMV-Mu γ into the BglII/NheI site of pCpG-mcs (InvivoGen, San Diego, CA) [25].

***In vivo* gene transfer of IFN- γ**

Naked plasmid DNA dissolved in isotonic saline solution was injected into the tail vein of mice over 5 sec on day 0 [27, 28]. To adjust the peak level of the IFN- γ concentration after gene transfer, the plasmid dose was fixed at 0.05 and 4.68 pmol/mouse for pCpG-Mu γ and pCMV-Mu γ , respectively, based on preliminary experiments. pCMV-Mu γ was injected twice at an interval of 1 week (days 0 and 7). The body weight and temperature of mice were measured to assess the adverse effects of IFN- γ gene transfer.

Measurement of concentration of IFN- γ , IgE, and IL-4, -12, and -13

Blood samples were obtained from the tail vein at indicated times after gene transfer, kept at 4°C for 2 h to allow clotting, and then centrifuged to obtain serum. Dorsal skin tissue was homogenized in PBS containing protease inhibitors (protease inhibitor mixture; Sigma-Aldrich, Munich, Germany) and then centrifuged for 30 min at 12,000 \times g. The concentration of IFN- γ , IgE, and IL-4, -12, and IL-13 in the serum or supernatant of skin homogenate was measured using ELISA kits (Ready-SET-Go! Mouse IFN- γ , IL-4 and IL-13 ELISA, eBioscience, San Diego, CA; OptEIA set Mouse IL-12 and IgE, BD Biosciences, San Jose,

CA) according to the manufacturer's instruction.

mRNA quantification

Total RNA was extracted from approximately 100 mg spleen or skin sample using Sepasol RNA I Super (Nacalai Tesque, Kyoto, Japan). The total RNA was cleaned up using an RNeasy mini kit (Qiagen, Hilden, Germany). Reverse transcription was performed using a SuperScript II (Invitrogen) and oligo (dT) primer, according to the manufacturer's protocol. For a quantitative analysis of mRNA expression, real-time PCR was carried out with total cDNA using a LightCycler instrument (Roche Diagnostics, Basel, Switzerland). The oligonucleotide primers used for amplification are listed in Table 1. Amplified products were detected online via intercalation of the fluorescent dye SYBR green (LightCycler-FastStart DNA Master SYBR Green I kit, Roche Diagnostics, Indianapolis, IN). The cycling conditions were as follows: initial enzyme activation at 95°C for 10 min, followed by 45 cycles at 95°C for 10 sec, 60°C for 5 sec, and 72°C for 20 sec. The mRNA expression of genes of interest was normalized using the mRNA level of β -actin.

Scoring skin lesions

Skin lesions were scored at indicated times after gene transfer, according to the criteria of Matsuda et al [7]. The scoring was based on the severity of eczema, erosion/excoriation, scaling, erythema/hemorrhage, inflammation of the face, and inflammation of the ear. The total clinical skin severity score was defined as the sum of each of the six signs (none = 0; mild = 1; moderate = 2; and severe = 3).

Observation of scratching behavior

On days 7, 14, and 35, scratching behavior was monitored using SCLABA Real (Noveltec, Kobe, Japan), an automated system to analyze the scratching behavior of small animals. Each mouse was put into an acrylic cage, and the behavior of the mice was recorded for 30 min. The number of episodes and the duration of scratching behavior were automatically quantified. In a different set of mice, the scratching behavior was recorded on video for 1 hr on days 7, 14, 35, and 84. The videotape was played back at a later time, and the number of scratching episodes was counted manually. A series of scratching behaviors, starting with the stretching of the hind paws to the head, face, or back and ending with the set-back of the paws, was counted as one bout of scratching [29].

Measurement of TEWL

TEWL was measured using a VAPO SCAN (AS-VT 100RS, Asahi Biomed, Yokohama, Japan) on the shaved back of mice.

Analysis of skin sections

The dorsal skin of the mice was excised, fixed in 4% paraformaldehyde, and embedded in paraffin. Then, 4 μm -sections were made using a microtome and stained with H&E for histological evaluation or with toluidine blue to detect mast cells. The numbers of lymphocytes, eosinophils, and mast cells on H&E-stained sections (lymphocytes and eosinophils) or toluidine blue-stained sections (mast cells) were manually counted under a microscope and expressed as the number per unit length of skin section.

Effect of IFN- γ gene transfer on 2,4,6-trinitrochlorobenzene-induced dermatitis

To assess whether IFN- γ gene transfer increases the risk for contact dermatitis, C57BL/6 mice were sensitized by painting 25 μl 3% 2,4,6-trinitrochlorobenzene (TNCB) in acetone/olive oil (4:1) on the shaved abdomen (day 0). pCpG-Mu γ was injected by the hydrodynamic injection method to TNCB-treated mice 1 day before or 7 day after the TNCB treatment, at a dose of 0.14 $\mu\text{g}/\text{mouse}$. On day 5, the thickness of the ear was measured with a Quick Mini thickness gauge (Mitutoyo, Tokyo, Japan). Then, 20 μl 1.5% TNCB solution was applied to the surface of the ear. The thickness of the ear was measured again 24 h after the second application (challenge), and ear swelling was evaluated by the difference in the thickness before and after the challenge.

Effect of IFN- γ gene transfer on TEWL in tape stripping- and TNCB-induced dermatitis models

C57BL/6 mice were shaved on their dorsal skin on day 0 and injected with pCpG-Mu γ (0.14 $\mu\text{g}/\text{mouse}$) or saline by the hydrodynamic injection method on the same day. Mice were repeatedly treated with 50 μl 1% TNCB dissolved in acetone/olive oil (4:1) to the shaved skin on days 1, 8, 11, and 13. In a separate experiment, the dorsal skin of C57BL/6 mice was tape stripped on days 1 and 8 and injected with pCpG-Mu γ (0.14 $\mu\text{g}/\text{mouse}$) or saline by the hydrodynamic injection method on day 0. TEWL from the stripped or shaved skin was measured as described above.

Statistical analysis

Differences were evaluated by the Student t test, and the level of statistical significance was $p < 0.05$.

I-1-3 Results

I-1-3-a. IFN- γ concentration in the serum of NC/Nga mice after injection of IFN- γ -expressing plasmid DNA

Fig. 1 shows the time courses of the concentration of IFN- γ in the serum after intravenous injection of pCpG-Mu γ or pCMV-Mu γ . A very high and sustained concentration of IFN- γ was detected in the serum of mice receiving pCpG-Mu γ at a dose of 0.05 pmol/mouse . The concentration of IFN- γ was maintained at more than 300 pg/ml over 80 days after a single injection. However, the concentration of IFN- γ had decreased very quickly below the detection limit (25 pg/ml) 3 days after the first injection of pCMV-Mu γ (4.68 pmol/mouse). The plasmid was injected again 1 week later, but the peak level was lower than that after the first injection, and the concentration decreased quickly again.

FIGURE 1. Time-course of the concentration of IFN- γ in mouse serum after injection of IFN- γ -expressing plasmid DNA. NC/Nga mice were intravenously injected with 0.05 pmol pCpG-Mu γ (●) or 4.68 pmol pCMV-Mu γ (□) by the hydrodynamic injection method. The pCMV-Mu γ -injected group received a second injection of 4.68 pmol pCMV-Mu γ 7 days after the first injection (indicated with a dashed line and an arrow). The results are expressed as the mean \pm SD of five mice.

I-1-3-b. IL-12 concentration in the serum of NC/Nga mice after injection of IFN- γ -expressing plasmid DNA

It would be expected that a persistent expression of IFN- γ would induce the expression of IL-12, a typical Th1 cytokine that promotes the differentiation of naive T cells into the Th1 phenotype. Therefore, the serum concentration of IL-12 was measured (Fig. 2a). The IL-12 concentration in the untreated group was not constant during the experimental period; it fluctuated, reflecting the acute and chronic phases of the disease [30]. The concentration of IL-12 was significantly increased in the pCpG-Mu γ -treated group from days 3 to 42 after injection. The concentration in the pCMV-Mu γ -treated group was significantly greater 3 days after the first injection compared with that in the untreated group; thereafter, the profile became superimposed on that of the untreated group. The second injection of pCMV-Mu γ on day 7 barely affected the serum concentration of IL-12.

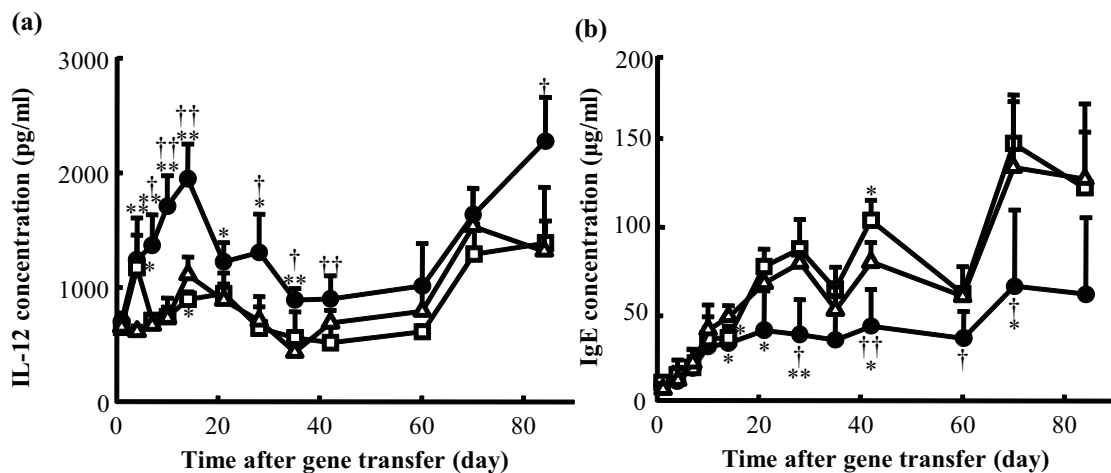

FIGURE 2. Time-course of the concentration of IL-12 (a) and IgE (b) in mouse serum after injection of IFN- γ -expressing plasmid DNA. NC/Nga mice were intravenously injected with 0.05 pmol pCpG-Mu γ or 4.68 pmol pCMV-Mu γ as described in the legend of Fig. 1. Blood samples from the untreated (Δ), the pCpG-Mu γ -injected (●) or the pCMV-Mu γ -injected (\square) mice were collected from the tail vein at indicated times after gene transfer. The results are expressed as the mean \pm SD of at least three mice. * P <0.05, ** P <0.01 compared with the untreated group; † P <0.05, †† P <0.01 compared with the pCMV-Mu γ -treated group.

I-1-3-c. IgE concentration in the serum of NC/Nga mice after injection of IFN- γ -expressing plasmid DNA

Next, the concentration of IgE, a diagnostic marker of atopic dermatitis [31], was measured in the serum, because increased IgE production is a hallmark of Th2 immune responses. Fig. 2b shows the concentration of IgE in the serum of the untreated mice or mice treated with pCpG-Mu γ or pCMV-Mu γ . The concentration at the onset of treatment was about 10 μ g/ml, and it increased with time to more than 100 μ g/ml in the untreated group. It also increased in the treated groups, but the increase was significantly inhibited in the pCpG-Mu γ -treated group from day 14 after the treatment. In addition, I measured the serum concentrations of IL-4 and -13, which play important roles in the regulation of IgE synthesis [32, 33]. However, the concentrations of IL-4 and -13 in the serum of all groups were below the detection limit (4 pg/ml) of the analysis.

I-1-3-d. mRNA expression of cytokine and chemokine in spleen cells of NC/Nga mice after injection of IFN- γ -expressing plasmid DNA

The effect of IFN- γ gene transfer on the expression of cytokines/chemokines was evaluated by measuring the mRNA expression of IL-12, Th2 cytokines (IL-4, -5, -10, and -13), IL-17, and a Th2 chemokine (TARC) in spleen cells collected from mice 14 days after gene transfer using the primers listed in Table 1. The mRNA expression of these genes in spleen cells was normalized to that of β -actin, and the ratios were compared between the untreated and the pCpG-Mu γ -treated mice (Fig. 3). The differences between the groups were very large for IL-5, -10, -12, and -13 and TARC, although they were not statistically significant because of the limited number of samples. The IL-12 mRNA expression was increased by injection of pCpG-Mu γ , which was in good agreement with the serum level of IL-12 (Fig. 2a). The mRNA expression of IL-4, -5, -10, -13, and -17 and TARC in the pCpG-Mu γ -treated group was lower than that in the untreated group. The mRNA expression in spleen cells 40 days after gene transfer showed no significant differences (data not shown). In addition, the expression of these cytokines in the skin was examined by ELISA and RT-PCR 40 days after gene transfer. However, no significant differences were detected among the groups (data not shown).

FIGURE 3. mRNA expression of cytokines and TARC in spleen cells. Spleens from NC/Nga mice receiving 0.05 pmol pCpG-Mu γ were collected 14 days after gene transfer, and the mRNA expression of cytokine and chemokine genes was measured by real-time PCR. The mRNA expression of genes was normalized using the mRNA level of β -actin. In comparison, spleens from untreated mice were treated as above. (a) IL-12, (b) IL-4, (c) IL-5, (d) IL-10, (e) IL-13, (f) IL-17, and (g) TARC. U, untreated mice; CpG, pCpG-Mu γ -injected mice. The results are expressed as the mean \pm SD of three mice.

I-1-3-e. Skin lesions of NC/Nga mice after injection of IFN- γ -expressing plasmid DNA

The results indicated that the Th1/Th2 balance can be shifted to Th1 in the atopic dermatitis model by sustained, but not transient, transgene expression of IFN- γ . The effects of gene transfer on atopic dermatitis were examined in NC/Nga mice. Fig. 4 shows the typical images of the back skin of mice 35 days after the start of treatment. Clinical signs and symptoms were clearly seen on the skin of the untreated mice (Fig. 4a) and the pCMV-Mu γ -treated mice (Fig. 4c), indicating that these mice developed a severe dermatitis. The severity of skin damage was scored using a clinical skin score [7]. The untreated and the pCMV-Mu γ -treated groups developed dermatitis within a week after the start of the experiment, and the severity of the dermatitis increased with time (Fig. 4d). In contrast, the pCpG-Mu γ -treated mice developed much less severe skin inflammation throughout the experimental period (Fig. 4b), and the clinical skin score of the group was significantly lower than that of the untreated or the pCMV-Mu γ -treated group (Fig. 4d).

FIGURE 4. Typical images of the back skin of NC/Nga mice (a-c) and the time-course of the skin clinical score (d). Photographs were taken at 35 days after the start of treatment: (a) untreated mice, (b) pCpG-Muγ-treated mice and (c) pCMV-Muγ-treated mice. (d) Clinical features of dermatitis were scored at indicated periods of time after the start of treatment. The results are expressed as the mean \pm SD of at least three mice. * $P < 0.05$, ** $P < 0.01$ compared with the untreated group; † $P < 0.05$, †† $P < 0.01$ compared with the pCMV-Muγ-treated group.

I-1-3-f. Scratching behavior of NC/Nga mice after injection of IFN- γ -expressing plasmid DNA

Fig. 5 shows the number of episodes of scratching and the cumulative time of scratching for a 30-min period. The number and duration of scratching episodes increased with time in the untreated group. The pCpG-Muγ- and pCMV-Muγ-treated groups had significantly fewer episodes and shorter duration of scratching than the untreated group, with significantly better results for pCpG-Muγ-treated mice. Similar results were obtained in a different set of mice whose scratching episodes were counted manually after videotaping (data not shown).

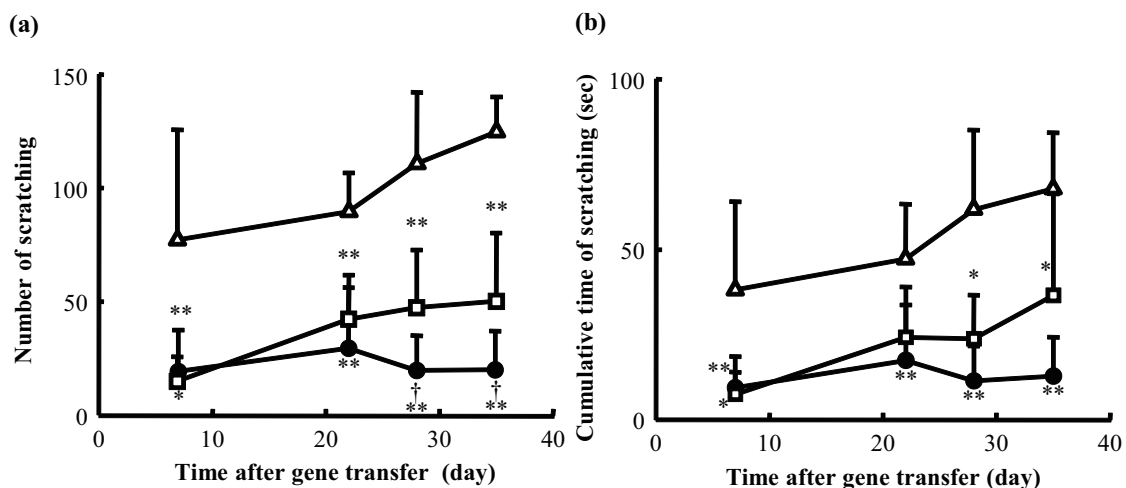

FIGURE 5. Number (a) and cumulative time (b) of scratching episodes. Scratching behavior of NC/Nga mice treated as described in the legend of Fig. 1 were automatically evaluated using SCLABA-Real. (Δ) untreated mice, (\bullet) pCpG-Mu γ -treated mice and (\square) pCMV-Mu γ -treated mice. The results are expressed as the mean \pm SD of at least three mice. * $P < 0.05$, ** $P < 0.01$ compared with the untreated group; † $P < 0.05$ compared with the pCMV-Mu γ -treated group.

I-1-3-g. TEWL of NC/Nga mice after injection of IFN- γ -expressing plasmid DNA

Dry skin is a common symptom of atopic dermatitis, which is characterized by extensive water loss through the skin. Thus, the TEWL of the skin was measured on the back (Fig. 6). The TEWL value at day 0 was about 10 g/h/m² in all groups. In the untreated mice, the value increased to more than 50 g/h/m² by day 14, and an almost constant value was observed in the period that followed. The elevation of TEWL was significantly inhibited in the pCpG-Mu γ -treated group throughout the experimental period. The TEWL of the pCMV-Mu γ -treated mice was as low as that of the pCpG-Mu γ -treated ones for the first 14 days, but it was significantly higher at days 70 and 84.

FIGURE 6. Time-course of the TEWL of the back skin of mice. TEWL of the skin was measured in the back of untreated mice (Δ), pCpG-Mu γ -treated mice (\bullet) and pCMV-Mu γ -treated mice (\square). The results are expressed as the mean \pm SD of at least three mice. ** $P < 0.01$ compared with the untreated group; †† $P < 0.01$ compared with the pCMV-Mu γ -treated group.

I-1-3-h. Histological examination of skin sections of NC/Nga mice after injection of IFN- γ -expressing plasmid DNA

Fig. 7 shows the H&E sections of the back skin of treated and untreated mice at day 14 after the start of treatment. NC/Nga mice maintained under specific pathogen-free (SPF) conditions were used as control mice with healthy skin; the skin sections from the SPF control mice showed no pathological features (Fig. 7a). In marked contrast, there was clear hyperplasia of the epidermis (acanthosis) in the untreated group (Fig. 7b). The sections from the untreated mice also showed an extensive infiltration of lymphocytes and eosinophils. These characteristic features of inflamed skin tissues were not as apparent in the skin sections from the pCpG-Mu γ -treated mice (Fig. 7c), which were indistinguishable from the skin sections from the SPF control mice. Compared with the sections from the pCpG-Mu γ -treated mice, the ones from pCMV-Mu γ -treated mice showed less significant improvement (Fig. 7d). Fig. 8 shows the skin sections in which mast cells were stained with toluidine blue. Again, a significant infiltration of mast cells was observed in the untreated mice (Fig. 8b), but not in the SPF control (Fig. 8a) or the pCpG-Mu γ -treated mice (Fig. 8c). The numbers of lymphocytes, eosinophils, and mast cells in skin sections were counted (Fig. 9). The numbers of these cells were significantly less in mice receiving IFN- γ -expressing plasmid DNA compared with untreated mice.

FIGURE 7. Hematoxylin and eosin sections of the back skin of NC/Nga. Dorsal skin of mice maintained under SPF conditions (a), untreated mice (b), pCpG-Mu γ -treated mice (c) and pCMV-Mu γ -treated mice (d) were collected at day 14. Skin sections were stained with hematoxylin and eosin for histological evaluation and detection of inflammatory cells.

FIGURE 8. Toluidine blue sections of the back skin of NC/Nga. Dorsal skin of mice maintained under SPF conditions (a), untreated mice (b), pCpG-Mu γ -treated mice (c) and pCMV-Mu γ -treated mice (d) were collected at day 14. Skin sections were stained with Toluidine blue to detect mast cells.

FIGURE 9. Number of lymphocytes, eosinophils and mast cells in skin sections. Lymphocytes and eosinophils in hematoxylin and eosin-stained sections were counted under a microscope. The Toluidine blue sections were used for the counting of mast cells. The number of cells was expressed as mean \pm SD of three sections. Untreated mice (white bars), pCpG-Mu γ -treated mice (black bars), and pCMV-Mu γ -treated mice (gray bars). *P<0.05 and **P<0.01 compared with the untreated group.

I-1-3-i. Adverse effects of IFN- γ gene transfer

There were no significant differences in the body weight or temperature between the saline-injected mice and the pCpG-Mu γ -treated mice. To examine whether IFN- γ gene transfer increases the risk for contact dermatitis, the ear thickness was measured in a mouse model of TNCB-induced contact dermatitis. The challenge with TNCB significantly increased the thickness, but the injection of pCpG-Mu γ had no significant effects on the change (data not shown). Fig. 10 shows the time courses of the TEWL from the dorsal skin of tape stripped (Fig. 10a) or TNCB-treated mice (Fig. 10b). Again, no IFN- γ gene transfer-induced increase was observed in any case examined.

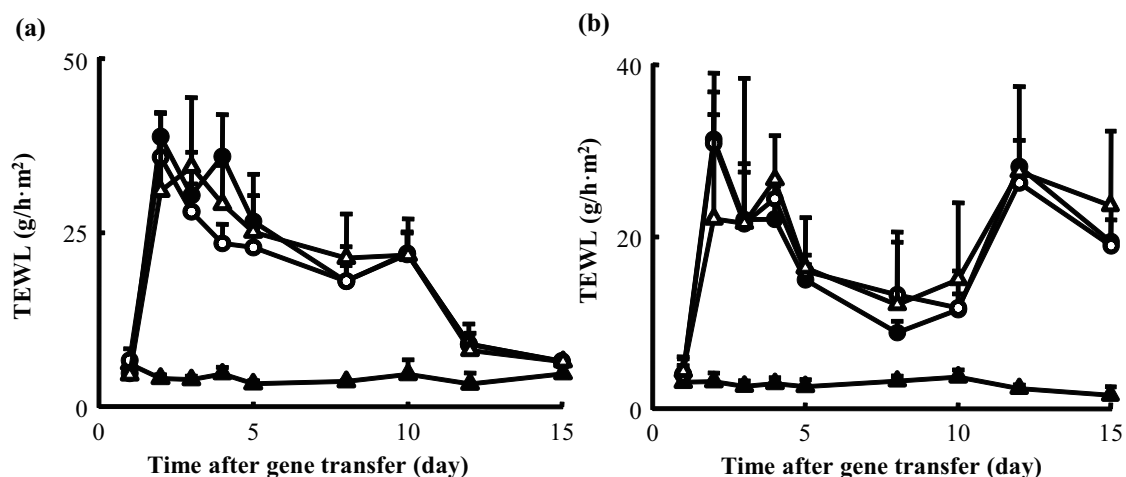

FIGURE 10. Time-course of the TEWL of the back skin of mice in a stripped skin (a) and a TNCB-induced dermatitis model (b). (a) The back skin of C57BL/6 mice was shaved and tape-stripped on days 1 and 8. (▲) untreated mice, (△) tape-stripped mice, (○) tape-stripped, saline-treated mice and (●) tape-stripped, pCpG-Muγ-treated mice. Results are expressed as mean ± SD of four mice. (b) The back skin of C57BL/6 mice was shaved and applied with TNCB on days 1, 8, 11 and 13. (▲) untreated mice, (△) TNCB-treated mice, (○) TNCB-treated, saline-treated mice and (●) TNCB-treated, pCpG-Muγ-treated mice. Results are expressed as mean ± SD of four mice.

I-1-4 Discussion

Because of the multiple functions of cytokines and their complicated network, the effects of externally administered cytokines, including IFN- γ , depend on their pharmacokinetics. Atopic dermatitis, a chronic inflammatory disease with skin inflammation, is characterized by Th2-dominant immunity; therefore, any treatment that normalizes the Th1/Th2 balance can be useful for treatment of the disease. IFN- γ , a typical Th1 cytokine, has been considered to induce a variety of immunological changes, leading to a Th1-dominant state, but its effects on the Th1/Th2 balance in patients with Th2 predominance is not fully understood. The outcome from the previous clinical experiments in which IFN- γ was administered to patients with atopic dermatitis suggested that there would be few significant changes in the immune system of the patients receiving such treatments [10-13]. This can primarily be attributed to the unfavorable pharmacokinetic properties of IFN- γ , which easily passes through the glomerulus of the kidney because it is smaller than the threshold of glomerular filtration, and it disappears from the systemic circulation very quickly [14].

In this section, a sustained level of IFN- γ in the serum was successfully achieved by injecting pCpG-Muγ. An IFN- γ concentration at more than 300 pg/ml, which is greater than the half maximal effective concentration of the protein needed to inhibit virus replication (100 pg/ml), was obtained throughout the experimental period of 84 days. This profile of IFN- γ in the serum was in marked contrast to that obtained by the injection of pCMV-Muγ, which resulted in a very transient IFN- γ concentration in the serum. Such a large difference in the duration of transgene expression is most likely due to the number of CpG motifs in plasmid DNA [24, 34]. A detailed discussion on this sustained expression of IFN- γ from pCpG-Muγ was presented elsewhere [25].

Sustained expression of IFN- γ from pCpG-Muγ induced a variety of immunological changes in NC/Nga mice. In summary, the level of Th1 cytokines IFN- γ and IL-12 (Fig. 2a) was increased and that of IL-4, -5, -10, -13, and -17 and TARC tended to be decreased (Fig. 3); thus, the Th1/Th2 balance shifted toward Th1 dominance. In addition, the level of IgE, a hallmark of allergic reactions, was also significantly decreased. These changes can be considered to be due to the biological activity of IFN- γ , which promotes the

production of IL-12, a typical Th1 cytokine important for differentiation to the Th1 subset. IL-12 is produced from macrophages or NK cells stimulated with IFN- γ . The reduced expression of the Th2 cytokines and TARC also resulted from the expression of IFN- γ , as reported using PBMCs, keratinocytes, or Langerhans cells [35, 36].

A major finding of this section is that the immunological changes induced by IFN- γ gene transfer differ, depending on the vector used (i.e., on the pharmacokinetics of IFN- γ). A variety of changes, including the increase in the IL-12 concentration and the decrease in the IgE level, were observed only in the mice receiving pCpG-Mu γ . These results clearly indicate the importance of a sustained concentration of IFN- γ at a level high enough to allow it to modulate the Th1/Th2 balance. In addition, these results may explain the fact that most challenges using IFN- γ protein for the treatment of atopic dermatitis are not very effective, because IFN- γ protein quickly disappears from the systemic circulation [14].

The modulation of Th1/Th2 imbalance by sustained expression of IFN- γ was significantly effective in preventing the onset of symptoms of atopic dermatitis in NC/Nga mice. Rash, scratching, bleeding on the back or ear, acanthosis, and infiltration of lymphocytes, eosinophils, and mast cells were not very apparent in the pCpG-Mu γ -treated mice. Inhibition of cellular infiltration into skin would be the consequence of the changes induced by the sustained concentration of IFN- γ ; this directly inhibits the infiltration of eosinophils [37, 38], and it could inhibit Th2 cell migration into skin promoted by Th2 chemokines [39-41]. Because Th2 lymphocytes are the cells that release Th2 cytokines [42], the findings in this section strongly suggest that IFN- γ gene transfer results in the inhibition of the differentiation of Th2 lymphocytes. Based on the results obtained, a mechanism of inhibition of atopic dermatitis by sustained expression of IFN- γ is proposed as follows. A sustained concentration of IFN- γ promotes the production of IL-12 from macrophages and NK cells, and these two Th1 cytokines inhibit the production of the Th2 cytokines/chemokines. These changes inhibit the recruitment of immune cells to the skin and prevent the onset of symptoms typical of atopic dermatitis. It is important to prove whether sustained IFN- γ gene transfer is also effective in individuals with dermatitis. Further studies are needed to conclude that IFN- γ gene transfer provides efficacy for patients with atopic dermatitis.

There would be concerns about sustained delivery of IFN- γ , because it is a highly potent Th1 cytokine. However, I observed no significant adverse effects of IFN- γ gene transfer on physiological parameters, such as body weight and body temperature. Also, contact dermatitis, a Th1-associated allergic dermatitis, was not aggravated by the injection of pCpG-Mu γ . In addition, the improvement in TEWL observed in NC/Nga mice receiving pCpG-Mu γ would not be due to the direct effects of IFN- γ gene transfer, because TEWL was minimally affected by IFN- γ gene transfer in other models (Fig. 10).

The hydrodynamic injection method used for gene transfer in the current study is one of the most efficient methods; using this method, >99% of transgenes were expressed in the liver, followed by kidneys, spleen, lung, and other internal organs [27, 43]. Although there is concern about the toxicity related to the mode of gene delivery [27, 28, 44, 45], a recent report showed that this method of gene delivery can be applied to humans with few toxic effects when plasmid DNA is delivered to a lobe using a balloon catheter [46]. Computer-assisted hydrodynamic gene delivery would also be a less invasive method [47]. Other modes for gene delivery could be used to achieve sustained transgene expression of IFN- γ at a relatively high level, because the dose of pCpG-Mu γ used was as low as 0.05 pmol or 0.14 μ g/mouse (i.e., approximately 7 μ g/kg body weight). In general, greater amounts of plasmid DNA up to 100 μ g/mouse (5 mg/kg) have been administered, and an increase in the dose may compensate for the low efficiency of other gene-delivery methods, such as intradermal injection of naked plasmid DNA.

In conclusion, it was proved that an extraordinarily sustained IFN- γ expression induces a variety of immunological changes, leading to a Th1-dominant state in the atopic dermatitis model. A short expression of IFN- γ was not effective in inducing such changes, indicating the importance of a sustained concentration of IFN- γ . These results provide a novel strategy for the treatment of atopic dermatitis, in which biologically active IFN- γ protein is supplied to patients from cells transduced with plasmid vector expressing the protein for a long period of time.

Section 2

Sustained IFN- γ expression improves symptoms of acute phase of atopic dermatitis

I-2-1 Introduction

In Section 1, I demonstrated that sustained expression of IFN- γ is effective in preventing the onset of symptoms of atopic dermatitis in NC/Nga mice [48]. To use IFN- γ gene transfer in the treatment of atopic dermatitis patients, it is important to show that such gene transfer is effective not only in preventing the onset of the disease but also in improving the symptoms.

Generally, atopic dermatitis is classified into two phases, acute and chronic. In the acute phase of atopic dermatitis, patients often have raised Th2 cytokines, such as IL-4, IL-5 and IL-13, which induce the class switching of B cells to IgE secretion, but low levels of IFN- γ or IL-12. In contrast, Th1 cytokines, especially IFN- γ , are dominant in chronic phase of atopic dermatitis [49-52]. Therefore, the administration of IFN- γ , a typical Th1 cytokine that shifts the differentiation of naive T cells to the Th1 subtype and suppresses the production of Th2 cytokines, appears to be an attractive option for the treatment of acute phase of atopic dermatitis [53, 54].

It has recently been shown that regulatory T cells (Tregs), a subset of T cells, are involved in the modulation of allergic diseases. For example, Tregs and their related cytokines, IL-10 and transforming growth factor (TGF)- β , have been reported to suppress Th2 responses and IgE production [55-57]. Furthermore, IFN- γ as well as the IL-12-specific receptor subunit β 2 plays important roles in the production of Tregs [58, 59].

In this section, I aimed to investigate whether IFN- γ gene transfer was able to effectively treat dermatitis induced in NC/Nga mice. To do this, I evaluated the serum levels of IgE and IgG1, the mRNA expression of Th1 and Treg cytokines, TEWL, the number of scratching episodes, the epidermal thickening, and the infiltration of inflammatory cells into the skin. In addition, the effect of sustained IFN- γ gene transfer on contact dermatitis was also examined to assess the safety of the gene transfer process.

I-2-2 Materials and Methods

Animals

Seven to eight week-old male NC/Nga mice and seven week-old female C57BL/6 mice were purchased and raised as described in Section 1. The NC/Nga group spontaneously developing dermatitis was used as a model of atopic dermatitis. The protocol for the animal experiments was approved by the Animal Experimentation Committee of the Graduate School of Pharmaceutical Sciences of Kyoto University.

In vivo gene transfer of IFN- γ

The naked plasmid pCpG-M μ y or pCpG-mcs (InvivoGen, San Diego, CA, USA) was injected into the tail vein of the mice by the hydrodynamic injection method, as described in Section 1, at a dose of 0.05 or 0.2 pmol/mouse on day 0.

Measurement of the concentrations of IFN- γ , IgG1 and IgE

The concentrations of IFN- γ and IgE in the serum were measured as described in Section 1. The concentration of IgG1 in the serum was measured using ELISA kits (Mouse IgG1 ELISA Quantitation Set, Bethyl Laboratories, Inc., Montgomery, TX, USA) according to the manufacturer's instructions.

Calculation of the pharmacokinetics parameters of IFN- γ gene transfer

The area under the concentration-time curve (AUC) and the mean residence time (MRT) of IFN- γ after gene transfer were calculated from the concentrations of IFN- γ in the serum of NC/Nga mice using moment analysis [60].

Real time PCR analysis of cytokine expression

RNA was extracted from approximately 100 mg of spleen samples using Sepasol RNA I Super (Nacalai Tesque, Kyoto, Japan). A mixture of recombinant DNase I-RNase-free (TAKARA, Shiga, Japan) and RNase OUT™ recombinant ribonuclease inhibitor (Invitrogen, Carlsbad, CA, USA) was used for DNase treatment. Reverse transcription was performed using a ReverTra Ace® qPCR RT Kit (TOYOBO, Osaka, Japan). The mRNA expression of genes of interest was analyzed using the quantitative real time PCR system as described in Section 1. The sequences of primers used for amplification are listed in table 2. Individual PCR products were analyzed by melting curve analysis and the length of the products was determined by agarose gel electrophoresis. The mRNA expression of each gene was normalized using the mRNA level of GAPDH.

TABLE 2. Primer sequences for quantitative RT-PCR.

Gene	Forward primer (5'→3')	Reverse primer (5' →3')

Scoring skin lesions

Skin lesions were scored at indicated times after gene transfer as described in Section 1.

Measurement of TEWL

TEWL was measured using an evaporimeter as described in Section 1.

Observation of scratching behavior

The scratching behavior was recorded on video for 30 min on days 15 and 21. The number of scratching episodes was counted manually as described in Section 1. On days 30, 33 and 35 after gene transfer, the scratching behavior was monitored using an automated system (SCLABA Real Noveltec Inc., Kobe, Japan) as described in Section 1.

Analysis of skin sections

The sections of dorsal skin of NC/Nga mice were prepared and stained for histological evaluation and quantification of the numbers of inflammatory cells infiltrating in the skins as described in Section 1.

Monitoring of adverse effects of IFN- γ gene transfer

The body temperature of the mice was monitored using a digital rectal thermometer (Physitemp Instruments Inc, Clifton, NJ, USA). To assess liver damage, the serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels of the mice were assayed using commercial test reagents (Transaminase CII-Test Wako, Wako Pure Chemical Industries, Osaka, Japan).

Oxazolone-induced contact hypersensitivity

The plasmid pCpG-Mu γ was injected into the tail vein of C57BL/6 mice (female, 7-week-old) by the hydrodynamic injection method at a dose of 0.2 pmol/mouse on day 0 or day 5. Mice were sensitized by the application of 100 μ l 2% oxazolone (OX) in ethanol (elicitation phase group) or ethanol alone (induction phase-group) to the shaved abdominal skin on day 1, followed by an application of 10 μ l 1% OX to the right ear on day 6. Ethanol was applied to the left ear. For the untreated group, ethanol was applied instead of oxazolone to the abdomen and right ear on either day 1 or 6. At 24 h after the second application, the thickness of both ears was measured using a digital thickness gauge (Quick Mini, Mitutoyo Co., Japan). Ear swelling was calculated from the difference in ear thickness between the hapten- and vehicle-treated ears.

Statistical analysis

Statistical significance was evaluated by ANOVA with a post-hoc Tukey-Kramer test for multiple comparisons (clinical skin scores) and Student's t-test for comparisons between two given groups. The level of statistical significance was set at $P < 0.05$.

I-2-3 Results

I-2-3-a. Time-course and pharmacokinetic parameters of IFN- γ after hydrodynamic injection of pCpG-Mu γ

Figure 11 shows the time-course of the concentrations of IFN- γ in the serum after hydrodynamic injection of pCpG-Mu γ . The serum levels of IFN- γ were dependent on the plasmid dose, and the higher dose of 0.2 pmol resulted in significantly higher concentrations for the first 4 days compared with the lower dose. The profiles were analyzed to obtain AUC and MRT values.

FIGURE 11. Time-course of the concentration of IFN- γ in serum of NC/Nga mice after hydrodynamic injection of 0.05 or 0.2 pmol pCpG-Mu γ . The results are expressed as the mean \pm SEM of five mice. # ## $p < 0.05, 0.01$, compared with the lower dose group.

Table 3 summarizes the maximum concentration (C_{max}), AUC and MRT after IFN- γ gene transfer. The C_{max} and AUC were increased by increasing the plasmid dose, whereas the MRT was hardly affected by the dose.

TABLE 3. C_{max}, AUC and MRT of serum IFN- γ after hydrodynamic injection of pCpG-Mu γ into mice

Dose (pmol/mouse)	C _{max} (ng/ml)	AUC (ng day/ml)	MRT (day)
0.05	21.3 \pm 1.5	71.3 \pm 7.9	4.67 \pm 0.78
0.2	54.0 \pm 10 ^a	204 \pm 35 ^b	4.21 \pm 0.70

The C_{max} values were obtained at 1 day after hydrodynamic injection of pCpG-Mu γ , and are expressed as the mean \pm standard error of the mean (SEM) of five mice. The AUC and MRT were calculated by moment analysis, and are expressed as the calculated mean \pm SEM of five mice. ^{a, b} p<0.05, 0.01, compared with the lower dose (0.05 pmol/mouse) group.

I-2-3-b. Effects of IFN- γ gene transfer on the skin lesions of NC/Nga mice

NC/Nga mice at the age of 7 to 8 weeks, which already developed atopic dermatitis-like symptoms, were used to assess the severity of skin lesions. Fig. 12 shows the time-course of the clinical skin score of NC/Nga mice after injection of pCpG-Mu γ . The score of mice treated with the lower dose pCpG-Mu γ increased with time and was not significantly different from that of the untreated mice for the first two weeks after gene transfer. These results contradicted those of Section 1, in which the lower dose of pCpG-Mu γ (0.05 pmol/mouse) was effective in preventing the onset of atopic dermatitis [48]. In contrast, the clinical skin score of mice receiving 0.2 pmol pCpG-Mu γ was significantly lower than those of the other two groups over the 5-week observation period. Based on these findings, the dose of the plasmid was set at 0.2 pmol/mouse in the subsequent experiments to study the therapeutic effects of pCpG-Mu γ in NC/Nga mice with dermatitis. To confirm the effects of IFN- γ , a control plasmid pCpG-mcs was administered to NC/Nga mice. However, the clinical skin score was hardly affected by this treatment (data not shown).

FIGURE 12. Time-course of the clinical skin score of NC/Nga mice after hydrodynamic injection of pCpG-Mu γ . The results are expressed as the mean \pm SEM of five (0.05 pmol and 0.2 pmol pCpG-Mu γ treated groups) and nine mice (the untreated group). *, **, ***p<0.05, 0.01, 0.001, compared with the untreated group; # ##p<0.05, 0.01, compared with the lower dose group.

I-2-3-c. Serum concentrations of IgG1 and IgE in NC/Nga mice after IFN- γ gene transfer

Fig. 13 shows the time-course of the concentration of IgG1 (Fig. 13a) and IgE (Fig. 13b) in the serum of NC/Nga mice after injection of pCpG-Mu γ . Both the serum levels of IgG1 and IgE of the pCpG-Mu γ -treated mice were significantly lower than those of the untreated mice at several time points, suggesting that the production of these Th2-mediated immunoglobulins in NC/Nga mice was at least partly inhibited by IFN- γ gene transfer.

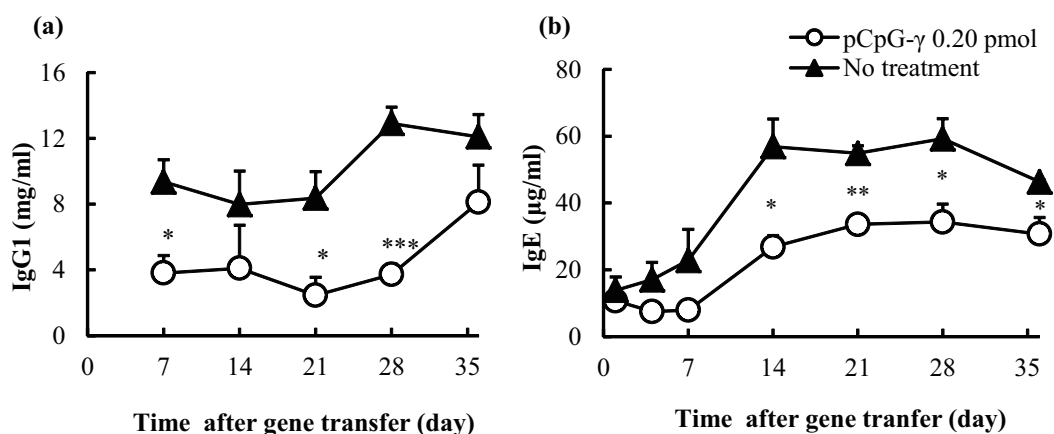

FIGURE 13. Time-course of the concentration of IgG1 (a) and IgE (b) in serum of NC/Nga mice after hydrodynamic injection of 0.05 or 0.2 pmol pCpG-Mu γ . The results are expressed as the mean \pm SEM of four mice. *, **, *** p <0.05, 0.01, 0.001, compared with the untreated group.

I-2-3-d. mRNA expression of Th1, Th2 and Treg cytokines in the spleen of NC/Nga mice after IFN- γ gene transfer

The high concentrations of IFN- γ in the serum were expected to induce the changes in the immunological status of NC/Nga mice. Therefore, the spleen, a major lymphoid organ, was excised and the mRNA expression of IFN- γ , IL-12, IL-4, IL-10 and TGF- β was measured. Fig. 14 shows the x-fold increase of mRNA expression by pCpG-Mu γ treated mice compared with untreated mice. The mRNA expression of IFN- γ and IL-12 in the pCpG-Mu γ -treated mice was, respectively, 3- and 1.7-fold higher than that in the untreated mice. In addition, the mRNA expression of IL-10 and TGF- β was also significantly higher in the pCpG-Mu γ -treated group. On the other hand, the mRNA expression of IL-4, a Th2 cytokine, was reduced to about half in the pCpG-Mu γ -treated mice.

FIGURE 14. mRNA expression of cytokines in spleen cells of NC/Nga mice. Spleens of untreated mice and pCpG-Mu γ treated mice were excised at day 36 after treatment. mRNA expression was normalized with that of GAPDH. The results are expressed as the mean \pm SEM of three (pCpG-Mu γ treated group) or four mice (the untreated group). * p <0.05 compared with the untreated group.

I-2-3-e. TEWL and scratching behavior of NC/Nga mice after IFN- γ gene transfer

To evaluate the severity of skin dryness and itchiness, the TEWL [61] and the number of scratching episodes were measured. Fig. 15a shows the time-course of the TEWL of NC/Nga mice from day 15 to day 35 after injection of pCpG-Mu γ . The TEWL value of the pCpG-Mu γ -treated mice was significantly lower than that of the untreated mice on days 15, 18, 21 and 35 after gene transfer. Fig. 15b shows the number of scratching episodes during a 30-min period of observation. The number of scratching episodes exhibited by the mice receiving pCpG-Mu γ was fewer than that of the untreated mice at all time points examined and the difference was significant on days 15 and 33 after injection of pCpG-Mu γ . These results indicate that IFN- γ gene transfer relieves the pruritus, a common symptom of atopic dermatitis that may lead to destruction of the skin barrier and is related to the increased TEWL of NC/Nga mice [62-64].

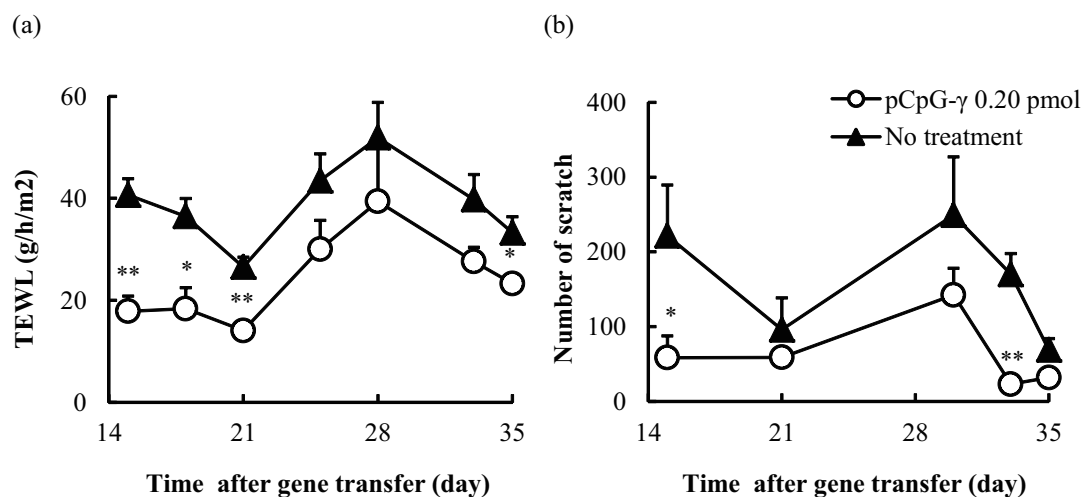

FIGURE 15. Time-course of the TEWL of the dorsal skin (a) and number of scratching episodes (b) of NC/Nga mice untreated or after hydrodynamic injection of 0.2 pmol pCpG-Mu γ . The results are expressed as the mean \pm SEM of four mice. *, ** p <0.05, 0.01, compared with the untreated group.

I-2-3-f. Histopathological examination of skin sections of NC/Nga mice

Fig. 16 shows the hematoxylin and eosin sections (Figs. 16a, b) and toluidine blue-stained sections (Figs. 16c, d) of the dorsal skin of NC/Nga mice at 36 days after treatment. The sections of the untreated mice showed obvious thickening of the epidermis (Figs. 16a, c). However, these characteristic features of skin inflammation were hardly seen in the sections from the pCpG-Mu γ -treated mice (Figs. 16b, d). Furthermore, the numbers of monocytes, granulocytes and mast cells in the skin sections were counted (Fig. 16e). The numbers of these cells infiltrating into the skin of the pCpG-Mu γ -treated animals were about a half those in the untreated mice, and there were significant differences between the groups with regard to the number of monocytes and mast cells.

FIGURE 16. H&E (a, b) and toluidine blue (c, d) sections of the dorsal skin of NC/Nga mice untreated (a, c) or pCpG-Mu γ -treated (b, d). Numbers of inflammatory cells in skin sections (E). The numbers of cells were expressed as the mean \pm SEM of three (pCpG-Mu γ -treated group) or four mice (the untreated group). * $p < 0.05$ compared with the untreated group.

I-2-3-g. Effect of IFN- γ gene transfer on body temperature and liver injury

The body temperature of the mice was measured to monitor the side effects of the high dose pCpG-Mu γ . No significant difference was observed in body temperature between the treated and untreated groups (data not shown). In addition, there were no significant differences in the serum AST and ALT levels between the pCpG-Mu γ -treated and the untreated groups (data not shown).

I-2-3-h. Effect of IFN- γ gene transfer on contact dermatitis

There are some concerns that IFN- γ gene transfer might increase the risk of Th1-associated diseases. To clarify this issue, the ear swelling response in the OX-induced contact dermatitis model was used to evaluate the contact hypersensitivity response in mice. As shown in Fig. 17, OX treatment induced ear swelling, but this response was not exacerbated by IFN- γ gene transfer.

FIGURE 17. Ear swelling response in OX-treated mice. pCpG-Mu γ was injected on day 0 or day 5. Mice were sensitized by OX or ethanol on the shaved abdomen on day 1 and on the right ear on day 6. Ear thickness was measured 24 h after the last OX application. Data are expressed as the mean \pm SEM of four mice.

I-2-4 Discussion

NC/Nga mice spontaneously develop atopic dermatitis-like skin lesions around the age of 6-8 weeks when raised under conventional condition. After that, the severity of the skin lesions and the parameters reflecting the severity, such as serum IgE level, increases with age. A previous study reported that the serum IgE levels of conventional NC/Nga mice increased markedly from 6 weeks of age to around 10 weeks and reached plateau at 17 weeks [8]. Thus the mice with atopic dermatitis at the age of 7 to 8 weeks, which were used in this study, represent a suitable model to evaluate the therapeutic effect of IFN- γ in the acute phase of atopic dermatitis. In this section, I demonstrated that pCpG-Mu γ is effective not only in preventing the onset of this condition but also in alleviating the symptoms of the disease, even though a higher dose of pCpG-Mu γ was required to treat the symptoms of NC/Nga mice with dermatitis. The mRNA expression of IFN- γ and IL-12, Th1 cytokines, in the spleen of mice receiving pCpG-Mu γ was increased and accompanied with a reduced expression of IL-4 mRNA in the spleen and reduced levels of serum IgG1 and IgE (Fig. 13). IFN- γ acts in conjunction with IL-12 by mediating a positive feedback loop to drive the Th1 response and inhibits IL-4 production by Th2 cells, resulting in the suppression of IgE and IgG1 secretion by B cells [41, 65, 66]. The mRNA expression of IL-10 and TGF- β , two representative Treg cytokines, in the spleen of mice receiving pCpG-Mu γ was also increased. It has been reported that Tregs inhibit Th2 cell function in allergic diseases by releasing IL-10 and TGF- β [57, 67]. The development of atopic dermatitis-like skin lesions in NC/Nga mice was suppressed by IL-10 expressing plasmid DNA [68]. It is possible that the increased expression of IFN- γ and IL-12 might induce Treg differentiation [58, 59] and partially contributed to these immunological changes by suppressing Th2 cell response. Taking all these findings into consideration, it is likely that IFN- γ gene transfer stimulates IL-12 production and these two Th1 cytokines act synergistically to polarize the T cell response toward Th1 subset and inhibit IgG1 and IgE production by suppressing the Th2 pathway. Further investigation is needed to prove whether the induction of Treg cytokines is related to these changes.

Scratching destroys skin barriers and worsens skin lesions [62, 64], which is closely linked to an increased TEWL. Histological examination of the skin sections clearly showed that IFN- γ gene transfer markedly suppressed skin inflammation and the infiltration of monocytes, granulocytes and mast cells. Mast cells can be sensitized by IgE and regulate the secretion of cytokines, such as IL-4, which subsequently mediates the recruitment of leukocytes [69], so that the reduced infiltration of these inflammatory cells into the skin could be due to the reduced production of IgE and IL-4. This suppression will prevent mice from scratching, which will accelerate skin repair and reduce TEWL. The number of scratching episodes of mice receiving pCpG-Mu γ was lower than that of the untreated mice at all time points, although it was fluctuated in the both groups. This could be explained by the difference in the time for measurement in each day [70], which was not be controlled in this study.

The use of IFN- γ as a therapeutic agent would be a double-edged sword. The need for a high dose of 0.2 pmol/mouse to treat, not to prevent, atopic dermatitis symptoms increases the chance of adverse reactions. The most common adverse events of IFN- γ therapy, which have been evidenced in several clinical trials, are “flu-like” symptoms, including fever, headache, fatigue, and myalgia. Diarrhea, erythema at the injection site, and the elevation of liver transaminase levels have also been reported in patients receiving the therapy. These common adverse events are generally transient and well tolerated [71-74]. In this section, I measured the body temperature and the liver transaminase levels in serum of mice for monitoring the signs of adverse events and demonstrated that IFN- γ gene transfer is safe for use in mice as long as the dose of the plasmid is 0.2 pmol/mouse or lower. However, the clinical skin score seems to return to baseline level at 4 weeks after treatment with this dose of plasmid (Fig. 12). This result may be explained by the reduction of IFN- γ levels in the serum of mice with time, thus increasing the dose of pCpG-Mu γ within the safety range could be an option to extend the duration of therapeutic effects. Recently, my laboratory has established a plasmid DNA expressing IFN γ in a constant manner with no initial high concentration of IFN- γ that could cause the unwanted effects [75]. This novel IFN- γ expressing plasmid would also be useful to enhance the therapeutic effect of IFN- γ . Another interesting point is that IFN- γ has been reported to be dominant in the skin of patients with chronic atopic dermatitis [52]. Further investigation is required to prove whether IFN- γ gene transfer is suitable for the treatment of chronic phase of atopic dermatitis.

In conclusion, I have demonstrated that sustained transgene expression of IFN- γ is effective in treating the atopic dermatitis in NC/Nga mice without any apparent adverse effects. These results raise a possibility that IFN- γ gene transfer can be a therapeutic option for patients with acute phase atopic dermatitis.

Chapter II

Effects of highly upregulated indoleamine 2,3-dioxygenase 1 on anti-tumor activity of IFN- γ gene transfer in tumor-bearing mice

II-1 Introduction

IFN- γ is a cytokine with antiproliferative and immunomodulatory activities. Therefore, it is expected to be used in treating a variety of diseases, including cancer [9, 76, 77]. In Chapter I, I showed that the hydrodynamic injection of pCpG-Mu γ resulted in prolonged therapeutic serum concentrations of IFN- γ for more than 80 days, and this significantly improved the symptoms of atopic dermatitis in NC/Nga mice. Previous studies in my laboratory demonstrated that sustained supply of IFN- γ effectively inhibited metastatic tumor growth in mice [24, 25].

IFN- γ exerts its biological activities through the Janus kinase/signal transducer and activator of transcription pathway, which modulates the expression of a variety of genes, including indoleamine 2,3-dioxygenase 1 (IDO1) [65, 78]. It was suggested that increased IDO activity is responsible for the protumor functions of IFN- γ [79-81]. However, little information is available about how IDO1 expression and/or activity is affected after IFN- γ gene transfer.

IDO1 is a tryptophan-metabolizing enzyme along the kynurenine pathway, and it is expressed in a variety of cells [82, 83]. The induced expression of IDO1 could lead to tryptophan depletion and formation of some toxic metabolites of tryptophan, such as kynurenine, and 3-hydroxykynurenine, which can result in the impairment of T cell functions and down-regulation of immune responses [84-87]. Various types of IDO1 inhibitors have been developed and reported to exhibit antitumor activity [82, 88-91]. However, the role of IDO1 in tumor growth is controversial so far [92]. Therefore, further investigation is needed to clarify the role of IDO1 in tumor development and its effects on the antitumor activity of IFN- γ .

Unpublished data from my laboratory showed that a hydrodynamic injection of pCpG-Mu γ increased the mRNA expression of IDO1 in liver, lung, kidney and spleen of naïve mice. This upregulation was associated with reduced tryptophan levels and increased kynurenine levels in serum of mice, indicating that IFN- γ gene transfer increased the IDO activity. Moreover, the mRNA expression of IDO1 in cultured LLC cells was also induced by IFN- γ gene transfer.

In this chapter, LLC tumor-bearing wild-type and IDO1-knockout mice were used to examine the involvement of IDO1 expression and activity in the antitumor effect of IFN- γ gene transfer. The serum concentrations of tryptophan and kynurenine were used to determine the IDO1 activity outside the tumor. Finally, the expression of IDO1 and concentrations of tryptophan and kynurenine in LLC tumor were also evaluated.

II-2 Materials and Methods

Mice

Five-week-old male C57BL/6J mice were purchased from Japan SLC, Inc. (Hamamatsu, Japan). IDO1 knockout (IDO1 KO) mice with a C57BL/6J background were obtained from the Jackson Laboratory

(Bar Harbor, ME, USA), bred and used at five weeks of age. Mice were maintained under conventional housing conditions. The protocols for animal experiments were approved by the Animal Experimentation Committee of the Graduate School of Pharmaceutical Sciences, Kyoto University.

Cell culture

Lewis lung carcinoma (LLC) cells were kindly provided by Dr. Kenichi Ogawara (Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama University) and cultured in Dulbecco's modified Eagle medium (DMEM; Nissui Co. Ltd., Tokyo, Japan) supplemented with 10 % heat-inactive fetal bovine serum (FBS) at 37°C, 5 % CO₂.

Plasmid DNA

Murine IFN- γ -expressing plasmid, pCpG-Muy was constructed as described in Chapter I, Section 1. Human IFN- γ -expressing plasmid, pCpG-Huy, which was used as a control plasmid, was constructed by inserting the human IFN- γ cDNA fragment amplified by the PCR into the multi-cloning site of the pCpG-mcs vector (Invivogen) [25, 26, 75].

***In vivo* gene transfer**

The naked plasmid was injected into the tail vein of the mice by the hydrodynamic injection method, as described in Chapter I, Section 1[27].

Measurement of serum concentrations of murine IFN- γ

The concentration of murine IFN- γ in the serum was analyzed using a commercial ELISA kit as described in Chapter I, Section 1.

Isolation of mRNA

Total RNA was extracted from approximately 100 mg liver, spleen, kidney, lung or tumor as described in Chapter I, Section 1.

Quantitative real-time PCR of mRNA

Real-time PCR was carried out as described in Chapter I, Section 1. The oligodeoxynucleotide primers used for amplification were as follows:

IDO1; forward, 5'-GCCTCCTATTCTGTCTTATGCAG-3',
reverse, 5'-ATACAGTGGGGATTGCTTTGATT-3', and
GAPDH; forward, 5'-ACGGATTTGGTCGTATTGGG-3',
reverse, 5'-CGCTCCTGGAAGATGGTGAT-3'.

The cycling conditions were as follows: initial enzyme activation at 95 °C for 10 min, followed by 45 cycles at 95 °C for 10 s, 60 °C for 5 s, and 72 °C for 15 s for IDO1. The cycling conditions for GAPDH was the same as those for IDO1 except for the annealing temperature of 56 °C. The mRNA expression of target genes was normalized using the mRNA level of GAPDH.

Measurement of concentrations of tryptophan and kynurenine in serum and tumor of mice

Serum samples (50 μ l) were mixed with 150 μ l 3% perchloric acid, incubated at 4 °C for 1 h, and then centrifuged at 18000 \times g for 10 min at 4 °C. The resulting supernatants were kept at -80°C until analysis.

For tumor samples, 50-100 mg tumors were homogenized in 2 volumes of KP buffer, then centrifuged at 12000 x g for 10 min at 4 °C. The supernatants were collected and mixed with 1 volume of 3% perchloric acid before analysis. The concentrations of tryptophan and kynurenine in supernatants were measured using HPLC with a spectrophotometric detector (Tosoh ultraviolet-8000, Tosoh, Tokyo, Japan) or a fluorescence spectrometric detector (Hitachi, Tokyo, Japan) [93]. Total protein concentrations in the tumor were measured using a protein assay kit (BioRad, Tokyo, Japan). The concentrations of tryptophan and kynurenine in the tumor were expressed as μmol per g tissue protein.

Antitumor effects of IFN- γ gene transfer

C57BL/6J and IDO1 KO mice were inoculated with 5×10^4 LLC cells into the dorsal skin. At 7 days after inoculation, mice were hydrodynamically injected with pCpG-Mu γ or pCpG-Hu γ at a dose of 0.23 $\mu\text{g}/20\text{g}$ body weight or injected with saline. The tumor size was monitored every two or three days, and the tumor volume was calculated from the equation: $(d_1 \times d_2)^{3/2} \times (\pi/6)$, where d_1 and d_2 are perpendicular tumor diameters [94]. The survival rate of the tumor-bearing mice was also recorded.

IDO1 expression in LLC tumor

C57BL/6J mice were inoculated with 5×10^4 LLC cells into the dorsal skin. Seven days later, the mice were hydrodynamically injected with pCpG-Mu γ or pCpG-Hu γ , which was used as a control plasmid in this study, at a dose of 0.23 $\mu\text{g}/20$ g body weight. At indicated times after gene transfer, solid tumors were dissected and the mRNA expression of IDO1 was measured as described above.

Statistical analysis

Statistical significance was evaluated by one-way ANOVA followed by Tukey's post hoc test for multiple comparisons and Student's *t*-test for comparisons between two given groups. The survival analysis was performed by LogRank test using SigmaPlot[®] 11.0. The level of statistical significance was set at $P < 0.05$.

II-3 Results

II-3-a. Antitumor effect of IFN- γ gene transfer in LLC tumor-bearing mice

To confirm whether IDO1 expression inhibits the IFN- γ -induced antitumor activity, I examined the antitumor effect of IFN- γ gene transfer in LLC tumor-bearing wild-type and IDO1 knockout (IDO1 KO) mice. Figs. 18a and 18b show the tumor growth curves of the wild-type and IDO1 KO mice, respectively, after gene transfer. The hydrodynamic injection of pCpG-Mu γ significantly retarded the tumor growth in both mouse strains without significant difference in tumor size. In contrast, the survival of the wild-type mice treated with pCpG-Mu γ tended to be increased by hydrodynamic injection of pCpG-Mu γ , whereas that of the IDO1 KO mice was hardly changed (Fig. 18c).

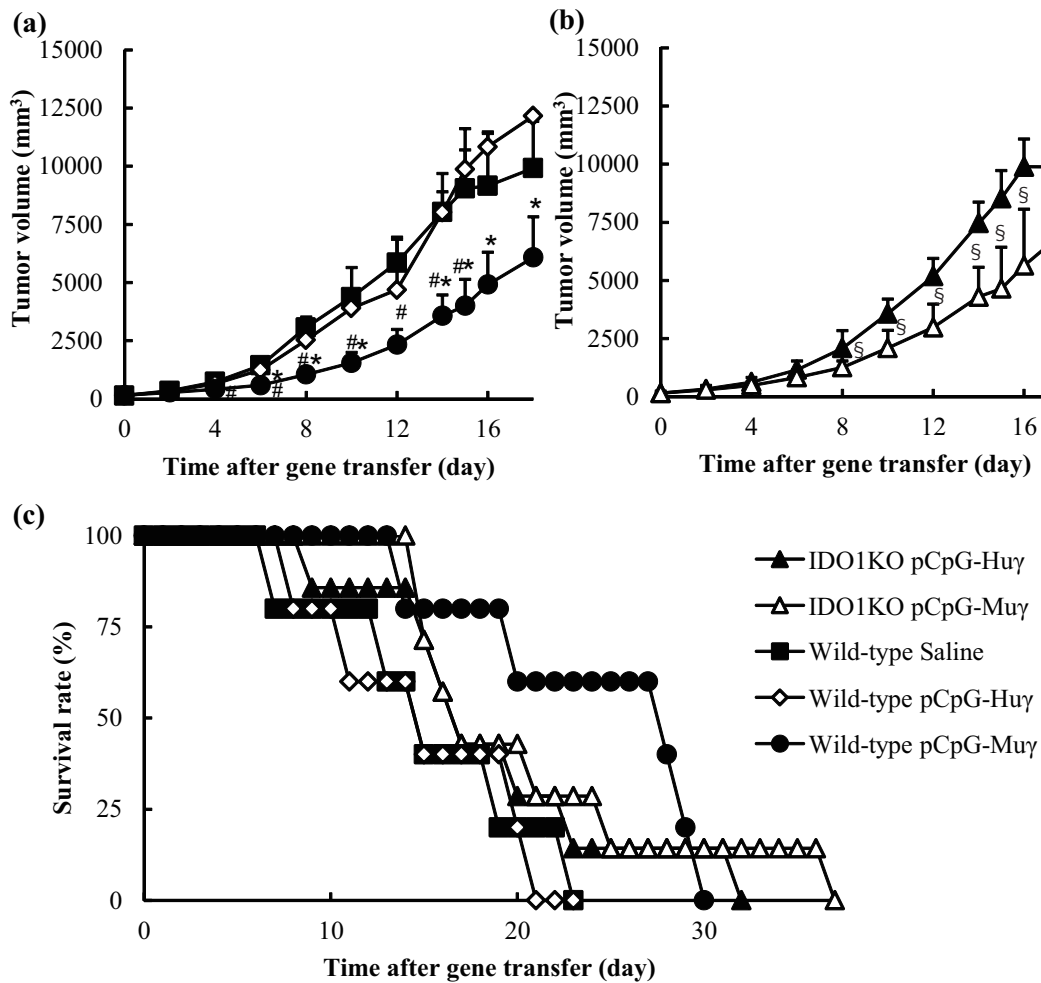

FIGURE 18. Tumor growth and survival of LLC tumor-bearing wild type and IDO1 KO mice after IFN- γ gene transfer. Wild-type (C57BL/6J) or IDO1 KO mice were injected intradermally with 5×10^4 LLC cells in the dorsal skin. Seven days later, mice were hydrodynamically injected with pCpG-Mu γ , pCpG-Hu γ or saline at a dose of $0.23 \mu\text{g}/20\text{g}$ body weight. The tumor size of wild-type (a) and IDO1 KO mice (b) was measured periodically and the survival of mice (c) was monitored. The results are expressed as the mean \pm SD of five mice for each group of wild-type mice and seven mice for each group of IDO1 KO mice. * $P < 0.05$ compared with the pCpG-Hu γ treated wild-type group, # $P < 0.05$ compared with the saline treated wild-type group, and $\text{§}P < 0.05$ compared with the pCpG-Hu γ treated IDO1 KO group.

II-3-b. Time-courses of serum concentrations of kynurenine and tryptophan of LLC tumor-bearing mice after IFN- γ gene transfer

To assess the IDO1 activity in these tumor-bearing mice, the concentrations of tryptophan and kynurenine in the serum were measured. As expected, there were no changes in the concentrations of tryptophan and kynurenine in the serum of IDO1 KO mice after the injection of pCpG-Mu γ , whereas the reduced tryptophan concentration and elevated kynurenine concentration were observed in the serum of wild-type mice receiving pCpG-Mu γ (Fig. 19). The baseline level of kynurenine in the serum of IDO1 KO mice was significantly lower than those of the wild-type mice (Fig. 19b), although the baseline levels of tryptophan in both strains were comparable (Fig. 19a), demonstrating a defect in kynurenine production in

the IDO1 KO mice. Finally, the kynurenine to tryptophan ratio hardly changed in the IDO1 KO mice receiving pCpG-Mu γ (Fig. 19c).

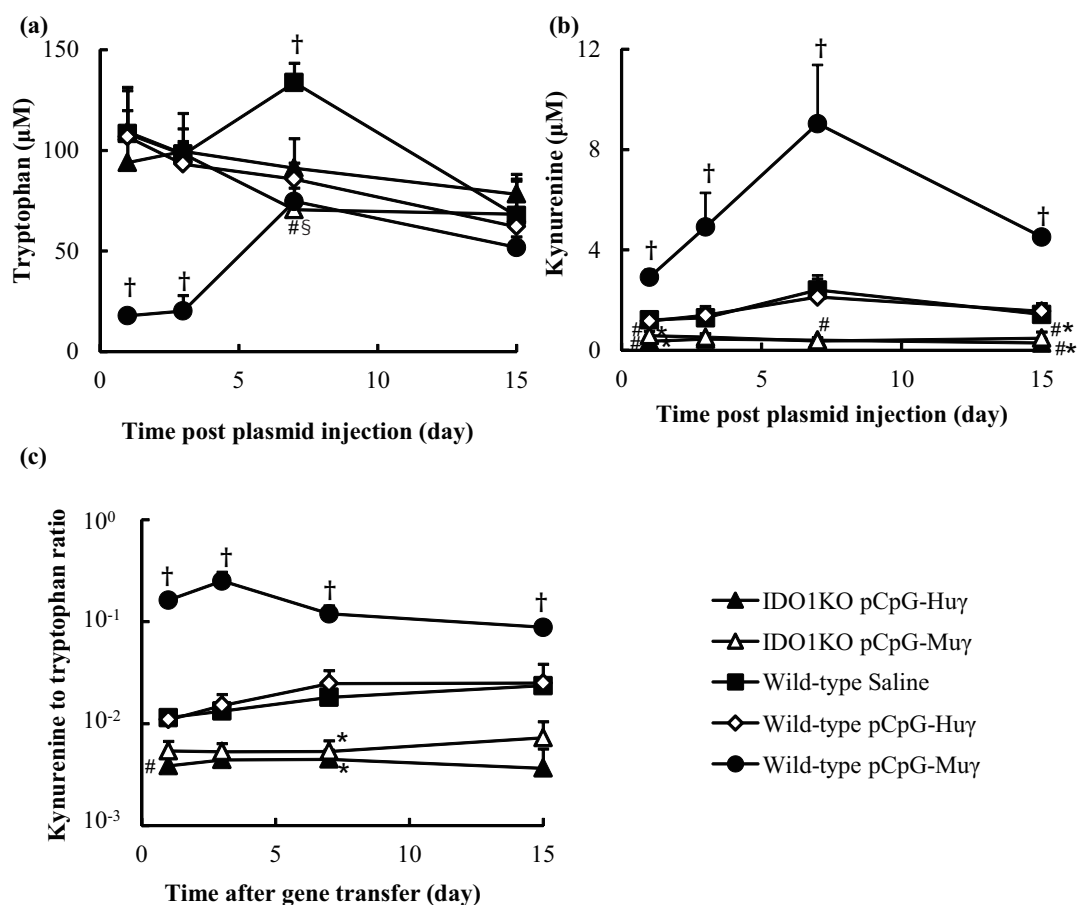

FIGURE 19. Time course of the concentrations of tryptophan (a) and kynurenine (b) in the serum and the ratio of kynurenine to tryptophan (c) of tumor bearing mice after IFN- γ gene transfer. The serum of mice was collected at indicated. The results are expressed as the mean \pm SD of five mice for each group of wild-type mice and seven mice for each group of IDO1 KO mice. *P<0.05 compared with the pCpG-Hu γ treated wild-type group, #P<0.05 compared with the saline treated wild-type group, §P<0.05 compared with the pCpG-Hu γ treated IDO1 KO group and †P<0.05 compared to all other groups.

II-3-c. Time-courses of IDO1 expression in LLC tumor of wild-type and IDO1 KO mice after IFN- γ gene transfer

To confirm whether IDO1 is expressed in the LLC tumor of IDO1 KO mice and is affected by IFN- γ gene transfer, the mRNA expression of IDO1 in LLC tumor was evaluated (Fig. 20a). The mRNA expression of IDO1 in the LLC tumor was detectable in both wild-type and IDO1 KO mice. The mRNA levels were comparable and almost constant in the control plasmid treated group of both strains. The hydrodynamic injection of pCpG-Mu γ significantly induced the expression of IDO1 in the tumor of the wild-type mice for up to 106, 59, and 74-fold at day 1, 3 and 7, respectively. On the other hand, the mRNA level of IDO1 in the tumor increased only about 7-fold in the IDO1 KO mice, but not statistically significant, and returned to the baseline level within 3 days after plasmid injection.

II-3-d. Concentrations of kynurenine and tryptophan in LLC tumor of wild-type and IDO1 KO mice after IFN- γ gene transfer

To evaluate the activity of IDO1 in the LLC tumor, the concentrations of tryptophan and kynurenine in the tumor were also measured (Figs. 20b-d). The concentrations of tryptophan in the LLC tumor at day 7 were comparable among all the groups (Fig. 20b). In response to the upregulation of IDO1 mRNA expression in LLC tumor by IFN- γ , the concentration of kynurenine in the LLC tumor of wild-type mice receiving pCpG-Mu γ was significantly increased for at least the first 14 days (Fig. 20c). Whereas in the IDO1 KO mice, the concentration of kynurenine in the LLC tumor returned to the baseline level within 7 days. Notably, there were no statistically significant differences between the baseline levels of kynurenine in the tumors of IDO1 KO mice and that of the wild-type mice. The kynurenine to tryptophan ratios in the tumor of these mice also revealed a similar trend (Fig. 20d). These results indicate comparable activity of IDO1 in the tumors of IDO1 KO mice and wild-type mice.

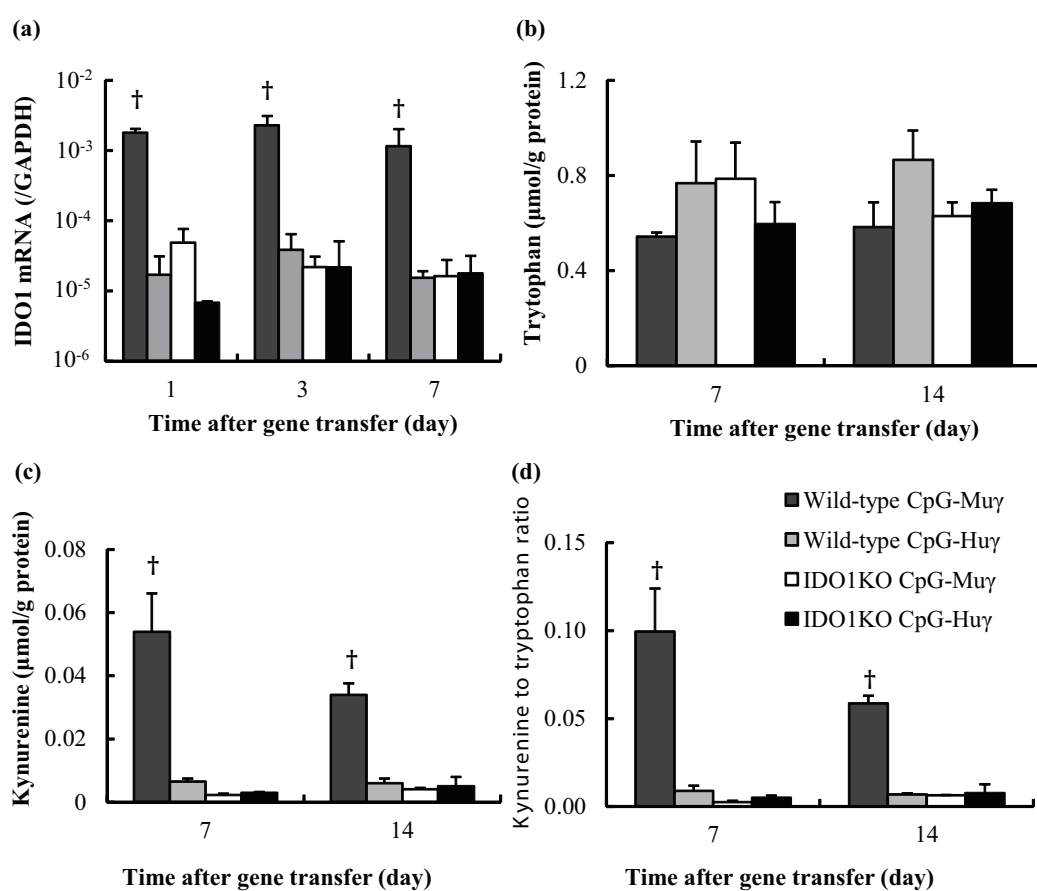

FIGURE 20. Levels of IDO1 mRNA, and concentrations of tryptophan and kynurenine in LLC tumor of tumor-bearing mice after IFN- γ gene transfer. LLC cells (5×10^4 cells per mouse) were injected intradermally in the dorsal skin. Seven days later, mice were hydrodynamically injected with pCpG-Mu γ or pCpG-Hu γ at a dose of 0.23 μ g/20 g body weight. The tumors were collected at indicated times, the levels of IDO1 mRNA (a) and the concentrations of tryptophan (b) and kynurenine (c) in the tumor were measured. The levels of IDO1 mRNA were normalized to GAPDH mRNA as an endogenous control. The concentration of tryptophan and kynurenine in the tumor were standardized per g total protein. The kynurenine to tryptophan ratios (d) were also calculated. The results are expressed as the mean \pm SD of four mice for the levels of IDO1 mRNA and three mice for the concentrations of tryptophan and kynurenine. †P<0.05 compared to all other groups.

II-4 Discussion

IFN- γ induces IDO1 expression in various mouse and human cells [95-98]. The unpublished results of my laboratory demonstrated that IFN- γ gene transfer dramatically increases the IDO1 expression in a variety of organs of mice. This IFN- γ gene transfer-mediated IDO1 upregulation was associated with reduced tryptophan levels and increased kynurenine levels in serum of naive mice. In this chapter, I found that these changes were hardly observed in the serum of the pCpG-Mu γ treated LLC tumor-bearing IDO1 KO mice, indicating that IDO1 is an only enzyme mediating tryptophan metabolism in response to IFN- γ gene transfer.

Irrespective to the IDO1 activity in serum, the growth of LLC tumor was significantly delayed by IFN- γ gene transfer in either wild-type and IDO1 KO mice with no statistically significant differences in tumor size between the groups (Fig. 18). These results imply that IFN- γ gene transfer-mediated IDO1 upregulation does not greatly affect the anti-tumor activity of IFN- γ . This observation is not in good agreement with a previous report by Gasparri et al., who showed that multiple injections of a recombinant murine IFN- γ fused with a tumor vascular homing peptide significantly induced IDOs activity in tumor, which consequently resulted in the ineffectiveness of IFN- γ activity against tumor outgrowth [79]. Although, the IDO1 expression and activity were induced in my study, I found that the increase of IDO1 expression and activity in tumor-bearing mice lasted for up to 14 days after IFN- γ gene transfer, even though the level of IFN- γ was maintained high for much longer. Therefore, the duration of upregulated IDO1 activity was shorter than IFN- γ activity and its role in the induction of tumor immune tolerance might be overcome by the sustained IFN- γ activity.

The previous study by Muller et al. demonstrated that IDO1 KO mice were resistant to skin tumor formation compared to their counterpart [99]. Smith et al. also reported that IDO1 KO mice showed reduced lung tumor burden and improved survival in models of primary lung carcinoma and breast carcinoma-derived pulmonary metastasis [100]. At first, I supposed that the loss of intact IDO1 could delay the tumor progression, even without IFN- γ treatment. Unexpectedly, I found no statistically significant differences in tumor growth rate and survival between the control plasmid treated-wild-type and IDO1 KO mice. Interestingly, it has been recently demonstrated that both IDO-competent and deficient mice bearing IDO-deficient brain tumors showed prolonged survival over those bearing IDO-competent brain tumors [101]. Similarly, Muller et al demonstrated that there were no differences in the tumor outgrowth and the response to 1-MT, between wild-type and IDO1 KO mice, which were engrafted with the IDO-overexpressed primary keratinocytes [102]. These reports strongly suggest that tumor-derived IDO1 activity is sufficient to mediate tumor immune tolerance and promote tumor progression, regardless of IDO1 expression outside the tumor. I also detected the IDO1 expression in the LLC tumor tissue of IDO1 KO mice (Fig. 20a), although IDO1 expression could not be detected in cultured LLC cells (unpublished data). These results suggest that the IDO1 in the engrafted LLC tumor cells is upregulated by their microenvironment, including tumor-infiltrating immune cells [95, 103]. Notably, the concentrations of kynurenine in the tumor of the control plasmid treated wild-type and IDO1 KO mice were comparable (Fig. 20c), even though there was a defective production of kynurenine in the serum of IDO1 KO mice (Fig. 19b). The comparable activity of IDO1 in the tumor of these mice can explain the comparable tumor outgrowth between the two strains and underlines the critical role of tumor-derived IDO1 on tumor progression.

The induction of IDO1 expression in LLC cells by IFN- γ could also be involved in the increase in the IDO1 mRNA expression in LLC tumors of both mouse strains, although mRNA level of IDO1 was lower and transiently expressed in the IDO1 KO mice (Fig. 20a). In the IDO1 competent mice, IDO1 could be

expressed, not only in the LLC cells, but also in the tumor-infiltrating immune cells, such as macrophages and dendritic cells [104, 105]. The differences in the type and number of IDO1-expressing cells could explain the different IDO1 mRNA levels in the tumor tissue of the pCpG- γ treated wild-type and IDO1 KO mice. Taken together, these findings suggest the role of tumor infiltrating immune cells to modulate IDO activity in tumor tissue, which could contribute to T cell proliferation inhibiting effect and promote tumor outgrowth. Further study is needed to investigate whether tumor-derived IDO1 lessens the antitumor activity of IFN- γ and if that is the case, a strategy for silencing IDO1 expression in tumor may be beneficial to enhance a potency of IFN- γ activity for cancer therapy.

In conclusion, IFN- γ gene transfer significantly upregulates the IDO1 expression in tumor and peripheral organs, but this up-regulation has only a marginal effect on both tumor growth and antitumor activity of IFN- γ .

Summary

The aim of this thesis was to study the beneficial effects of IFN- γ gene transfer in treating atopic dermatitis and cancer. The effectiveness of IFN- γ gene transfer in mouse models of the diseases could be achieved by the sustained supply of IFN- γ in serum of mice obtained from the hydrodynamic injection of pCpG-Mu γ . The main findings from each chapter are summarized as follows.

I. Improvement of atopic dermatitis by sustained exogenous expression of IFN- γ in NC/Nga mice via Th1 polarization.

The sustained, but not transient, transgene expression of IFN- γ can induce favorable immunological changes in a human atopic dermatitis model toward Th1-dominant state. The immunological changes, including the elevated level of IL-12, a Th1 driving cytokine, the reduced production of IgE, and inhibition of mRNA expression of Th2 cytokines, allowed the prevention of the development of atopic dermatitis-like skin lesions. This sustained expression of IFN- γ also markedly inhibited the epidermal thickening, infiltration of inflammatory cells into the skin, the occurrence of dry skin and pruritus in the NC/Nga mice with early dermatitis. No exacerbating effects on the Th1-mediated contact dermatitis were observed after IFN- γ gene transfer. Taken together, these results indicate that sustained IFN- γ gene transfer induced polarized Th1 immunity under Th2-dominant conditions in NC/Nga mice, leading to an improvement in the symptoms of acute atopic dermatitis without significant adverse side effects.

II. Effects of highly upregulated indoleamine 2,3-dioxygenase 1 on anti-tumor activity of IFN- γ gene transfer in tumor-bearing mice.

The sustained expression of IFN- γ greatly increased the mRNA expression of IDO1 in many tissues. This upregulation was associated with reduced tryptophan levels and increased kynurenine levels in serum, indicating that IFN- γ gene transfer increased the IDO1 activity. Then Lewis lung carcinoma (LLC) tumor-bearing wild-type and IDO1 knockout (IDO1 KO) mice were used to investigate the effects of IDO1 on the antitumor activity of IFN- γ . IFN- γ gene transfer significantly retarded the tumor growth in both mouse strains without significant difference in tumor size, although the IDO1 activity was increased only in the wild-type mice. Interestingly, IDO1 mRNA expression in the LLC tumor of IDO1 KO mice tended to increase by IFN- γ gene transfer, suggesting that the IDO1 expression in LLC cells was upregulated. Taken together, these results imply that IFN- γ gene transfer-mediated IDO1 upregulation hardly affect the antitumor activity of IFN- γ .

In conclusion, I demonstrated that sustained expression of therapeutic levels of IFN- γ was effective in preventing the onset of atopic dermatitis and improving the symptoms of the disease via Th1 polarization in the atopic dermatitis model. In addition, I also found that the sustained IFN- γ expression greatly upregulated IDO1, but this immune modulatory protein hardly affected the tumor growth in LLC tumor-bearing mice. Thus, this study provides evidence that IFN- γ gene transfer can be a useful treatment for the diseases.

Acknowledgments

I wish to express my heartfelt gratitude to Professor Yoshinobu Takakura for his excellent guidance, valuable discussion, warm support and encouragement throughout this study.

I owe a great debt to Associate Professor Makiya Nishikawa for his patient supervision, insightful comments and suggestions, persistent motivation and warm support facilitating the successful completion of this study.

I am further indebted to Assistant Professor Yuki Takahashi for his continuous support, inspiration, enthusiastic encouragement, and valuable guidance.

I would like to express my sincere thanks to Associate Professor Kenji Kabashima and Assistant Professor Akihiko Ikoma (Department of Dermatology, Graduate School of Medicine, Kyoto University), Professor Rei Takahashi (Department of Pharmacotherapeutics, Faculty of Pharmaceutical Sciences, Doshisha Women's College of Liberal Arts), and Professor Kuniaki Saito and his colleagues (Department of Human Health Sciences, Graduate School of Medicine and Faculty of Medicine, Kyoto University) for their collaboration, kind supports, helpful guidance and discussion.

I would also like to express my gratitude to Professor Mitsuru Hashida, Associate Professor Fumiyoshi Yamashita and Assistant Professor Shigeru Kawakami (Department of Drug Delivery Research, Graduate School of Pharmaceutical Sciences, Kyoto University) for their valuable supports.

This thesis would have not been possible without the scholarship and financial support for my higher graduate studies from Ministry of Education, Culture, Sports, Science and Technology of Japanese Government.

I am grateful for all warm supports and friendships of Dr. Lei Zang, Dr. Mitsuru Ando, Ms. Kayoko Hattori, and other colleagues, both the alumni and present members, of the Department of Biopharmaceutics and Drug Metabolism, Graduate School of Pharmaceutical Sciences, Kyoto University.

Last but not least, I would like to thank my beloved family and friends for their infinite love and spiritual support that have pushed me to strive harder through the difficult times during my study.
