We report on a deep level transient spectroscopy study of Cl-implanted n- and p-type 4H-SiC epilayers. Samples were electrically characterized after each step of an isochronal annealing series, between room temperature and 1800 °C, and twelve deep traps were detected. Of these, seven traps were found in n-type material, ranging from 0.15 to 1.6 eV below the conduction band minimum (EC), and five were detected in p-type material, located between 0.5 and 1.7 eV above the valence band maximum (EV). Besides the presence of the well known Z1/2 and EH0/7 levels in n-type 4H-SiC and of the D-center in p-type samples, we found that Cl implantation gives rise to three new traps in n-type material at EC − 0.37 eV, EV − 1.06 eV, and EC − 1.3 eV and one new level in p-type at EV + 0.97 eV. These traps are persistent after annealing at 1800 °C, and no data were found in the previous experimental studies reported in the literature. The possible involvement of Cl in the microscopic structure of these defects is discussed based on a depth profiling analysis of their concentration. © 2012 American Institute of Physics. I. INTRODUCTION

Nowadays, one of the biggest challenges of the SiC industry is supplying affordable material of very high crystalline quality. Standard growth techniques, such as chemical vapor deposition (CVD), allow growth rates ranging between 5 and 10 μm/h which are time consuming and not economically viable because high-voltage devices rely on very thick epilayers (~100 μm). In order to overcome this problem, it was shown1-4 that the use of chlorinated precursors can effectively increase growth rates up to 170 μm/h (Ref. 5) yielding good quality epilayers, without stacking faults.5 Additionally, the increase of the flow rate results in the formation of Si droplets,6 which, if not flushed away from the growth chamber, will eventually come into contact with the crystal surface giving rise to defects in the epilayers. To the contrary, by introducing Cl in the reactor in the form of HCl, CH3Cl, SiH4Cl, Cl, Cl can bind to Si and prevents the formation of the above mentioned droplets. This allows the increase of the flow rate resulting in an increase of the growth rates.

However, similarly to the case of H, which is present in the precursor gases and can be incorporated in SiC,7 also Cl can be incorporated in SiC during growth.5,8 Even if the detected concentration is close to, or below, the detection limit (~1014 cm−3),2 the possibility that Cl atoms are incorporated in the 1011 − 1012 cm−3 range cannot be excluded. This raises the question of whether or not Cl impurities give rise to electrically active defects, as is the case with H. The presence of electrically active levels in the band gap (EGAP) is a matter of extreme importance in device technology because they can act as charge carriers’ traps and harm the correct functionality of devices. However, despite the importance of this topic, scarce experimental and theoretical information is present in the literature.

La Via et al.4 have shown by deep level transient spectroscopy (DLTS) that both the Z1/2 and EH0/7 levels are present in n-type 4H-SiC grown by using HCl as a precursor and that new deep levels, related to Cl, are not observed, at least in the 1013 cm−3 range. Subsequently, by employing density functional theory (DFT), it was found that Cl preferably occupies a C-site rather than a Si-site and behaves as a triple donor.9 Furthermore, Cl easily binds to Al, giving rise to a very thermally stable complex defect, while it repels N (which is a donor itself).10 The donor character of Cl and Cl-related complexes10 can explain why the use of chlorinated precursors does not harm the net-donor concentration11 but cause the saturation of the net-acceptor concentration.12

In the following, we present a DLTS study on Cl-implanted n- or p-type 4H-SiC epilayers, annealed in 100 − 1800 °C temperature range, in order to shed the light on the possible presence of Cl-related electrically active defects in 4H-SiC.

II. EXPERIMENTAL DETAILS

We employed n- or p-type 4H-SiC epilayers doped with N or Al, respectively (N ≤ N ≤ 7 × 1015 cm−3). Epilayers were implanted with 700 keV Cl, which resulted in a mean projected range of 0.5 μm from the surface13 and with a dose of 5 × 1015 cm−2. Samples underwent an isochronal (15 min) annealing series in the 100 − 1800 °C temperature range (annealing step of 100 °C) in an Ar atmosphere. Heat treatments below 1000 °C were carried out in a rapid thermal annealing furnace (RTA) while for higher temperatures, a chemical vapor deposition chamber was employed. A carbon cap was deposited on the epilayer surface for temperatures above 1100 °C in order to minimize the effects of surface decomposition which was later removed by a dry oxidation process (1 h at 800 °C).14

After each annealing step, samples were dipped in HF for 10 min, and Au or Ti Schottky diodes were formed on the surface of n- and p-type 4H-SiC epilayers, respectively, by thermal evaporation. For p-type samples, ohmic contacts
were formed on the backside of the as-grown samples, by depositing a Ti/Al/Ni tri-layer sintered for 10 min at 1000 °C.

Electrical characterization was performed by capacitance-voltage (C-V) and Fourier-transform DLTS measurements. DLTS measurements were carried out in the 200-700 K temperature range, with a reverse bias of ±6 V (in order to cover the whole implantation range), a filling pulse to 0 V for 1 ms and a period width of 0.2 s. For annealing temperatures up to 400 °C, the highest DLTS temperature limit coincided with the annealing temperature.

III. RESULTS AND DISCUSSION

In Figs. 1(a) and 1(b), the results of the C–V measurements, for the as-grown and implanted n- and p-type 4H-SiC epilayers, are shown together with the implanted Cl and the total vacancies concentration profiles. The C–V profiles are obtained by changing the reverse bias up to 6 V (depletion width at 0 V ~ 0.4 μm) while the implanted Cl and total vacancies profiles are obtained from full-cascade SRIM simulations, in which the threshold displacement energies were set to 20 and 35 eV for C and Si, respectively. For n-type (Fig. 1(a)), the net-donor concentration (N_d) profile in the as-implanted sample is located well beyond the implanted zone, at a depth ranging between 0.8 and 1.3 μm. Subsequent heat treatments do not result in a significant donor reactivation closer to the implanted Cl profile. However, after annealing at 1400 °C, the N_d is reactivated at ~0.6 – 0.7 μm from the surface (shadowed area of Fig. 1(a)) where implanted Cl atoms are present in the 10^{12} – 10^{14} cm^{-2} range. A similar behavior is observed in the p-type sample for which higher annealing temperatures (1700 °C) are needed for the net-acceptor concentration (N_a) to be reactivated close to the Cl implanted profile. The lower concentration of Cl, with respect to that of either N_d or N_a, rules out the possibility that Cl itself may be responsible for the passivation of either N or Al. Furthermore, in the n-type material, it would be difficult for Cl to bind to N due to Coulombic repulsion. Instead, the absence of enhanced N_d (or N_a) signal in the implanted region may be due to the presence of compensating centers generated by implantation. As shown in Fig. 1, the total vacancy concentration is approximately ~3 × 10^{17} cm^{-3} and silicon vacancies (V_Si) that are present in a negative (positive) charge state in the upper (lower) half of the band gap of 4H-SiC, can be a cause for donor (acceptor) compensation. A similar analysis can be done for carbon vacancies (V_C) which, contrarily to V_Si, have a higher thermal stability. In addition, the formation of doping related complexes, arising after implantation, cannot be excluded: For instance, after implantation, N atoms can decorate V_Si yielding V_Si(N_C)\_x\_y (Ref. 20) which gives rise to an acceptor level in the upper half of the band gap and is thermally stable up to 2000 °C, while Al atoms can form Al/C\_i which yields a donor level in the lower half of the band gap and has also a high thermal stability (1700 °C).

Fig. 2 shows the DLTS spectra obtained in as-grown material and after annealing at 700, 1400, 1800 °C for n- and p-type 4H-SiC. In as-grown n-type 4H-SiC (Fig. 2(a)), the \( Z_{1/2} \) concentration \( 2 \times 10^{13} \) cm\(^{-3}\) and \( E_{H_{127}} \) (12 \( \times 10^{13} \) cm\(^{-3}\)) are detected while, for p-type, we have found the D-center \( (\sim 10^{12} \) cm\(^{-3}\)). After implantation (Fig. 2(b)), two levels are found in n-type 4H-SiC. The broad DLTS peak at 400 K \( (3 \times 10^{15} \) cm\(^{-3}\)) is identified as the \( E_{H_2} \) level, and a peak at \( \approx 575 \) K \( (\sim 10^{15} \) cm\(^{-3}\)), at 1.34 eV below the minimum of the conduction band \( (E_C) \), and labelled C1 which has not been reported earlier in the literature. In p-type material, we found one level labeled C12 \( (2 \times 10^{12} \) cm\(^{-3}\)) at 0.51 eV above the maximum of the valence band, \( E_V \), and another one identified as the UK2 center \( (2.5 \times 10^{12} \) cm\(^{-3}\)). Heat treatments at 1400 °C (Fig. 2(c)) results in the detection of the \( Z_{1/2} \) \( (5 \times 10^{14} \) cm\(^{-3}\)) and \( E_{H_{6/7}} \) \( (75 \times 10^{14} \) cm\(^{-3}\)) levels, for the n-type 4H-SiC epilayer, while the \( E_{H_4} \) is not detected at this annealing stage because it anneals out after 1200 °C. We note that the \( E_{H_{6/7}} \) level may have been overlapping with the C1 level and becomes clearly visible only after the annealing of C1. For this reason, we considered the spectrum at 1400 °C as the final annealing stage from which we subtracted the DLTS signal of the 700 °C annealed sample. The result of

![Graph](image_url)
the difference between the two DLTS spectra is shown by the broken line in Fig. 2(b) which may correspond to the real DLTS peak of the C11 level. For the p-type epilayer, the C12 and UK2 levels are still present, and a new level is found at ∼430 K and identified as the IM7 level (12, 13) (1013 cm−3). After the last annealing step (1800°C, Fig. 2(d)), the Z1/2, and EH6/7 are still detected in the n-type sample, and three new levels arise, labeled C13, C14, and C15 at 0.37 eV (1.4 × 1013 cm−3), 1.06 eV (2.4 × 1015 cm−3), and 1.3 eV (3.4 × 1013 cm−3) below Ec, respectively. For p-type samples, while the UK2 and IM7 are annealed out, the C12 is found to be persistent even after annealing at 1800°C and at the same time two other levels arise: One is labeled C16 at 0.97 eV (2.3 × 1012 cm−3) above Ev, and the other one is identified as the IM8 energy level (8) (8 × 1012 cm−3). A summary of the levels detected in the present study can be found in Table I.

Of all the levels, presently found in n-type 4H-SiC epilayers, the Z1/2, EH6/7, and EH8 have been reported earlier in a number of studies. It is well known that the Z1/2 possesses a negative-U behavior (18) and that its nature may be related to that of a carbon vacancy (VC). The broad EH6/7 is thought to be related to the Z1/2 center: Both Z1/2 and EH6/7 are present in either the as-grown or irradiated/implanted material, share the same annealing behavior (19), and their concentration is reduced when carbon interstitials, Ci, are injected into the epilayer. Compared to the Z1/2 and EH6/7, the EH8 has a lower thermal stability as it anneals out after heat treatments at 1200°C.

The trap labeled C11, found after Cl-implantation, has an energy position close to that of the EH5 (Ref. 22) and EH6/7 (Ref. 32) levels, but it has a higher thermal stability. In addition, C11 was detected in concentrations as high as 1015 cm−3, higher than that of the implanted Cl (1014 cm−3), and, for this reason, the possible involvement of Cl in its microscopic structure can be ruled out. On the contrary, since the C11 level has similar temperature position and thermal stability (both levels anneal out below 1700°C) of those of the IN8 level found by Kawahara et al. (23), we believe that C11 and IN8 levels may belong to the same defect. The C13 and C14 levels have a close energy position to that of the P3 and RD3 levels found in He+ implanted 4H-SiC (Ref. 34), but since they have a different annealing behavior (both P3 and RD3 anneal out at 1400°C), they are more likely to have different origins. Analogously to the C13 and C14, also for the C15 not much can be said on its microscopic nature. However, since these three levels have concentrations in the 1013 cm−3 range, the involvement of Cl in their microscopic structure may be more plausible. In fact, their detection coincides with the reactivation of Nd at 0.6 − 0.7 μm below the epilayer surface, and although neither theoretical nor experimental studies are present on Cl diffusion, the in-diffusion of Cl atoms at these temperatures cannot be excluded.

Much less is known on the nature of the traps detected in p-type 4H-SiC. The UK2, IM7, and IM8 have all been reported earlier: The UK2 was found in either electron irradiated (23) or hydrogen implanted (24) material, while the IM7 and IM8 were detected in hydrogen implanted samples. The UK2 was associated to a carbon-related complex and the IM7 to an Al-related complex, while no hypothesis on the nature of the IM8 level has been put forward yet. The level labeled C12 was found in the as-implanted material, and for this reason, the participation of Cl in its microscopic structure can be ruled out. Instead, we consider the possibility that it may be identified with the D-center because they are both thermally stable up to 1800°C, have similar energy position in the band gap, and the concentration of C12, in the as-implanted sample (2 × 1015 cm−3), is very similar to that of the D-center found in as-grown samples. Regarding the C16 level, we exclude that this level could be identified with the IP6 level found in implanted p-type 4H-SiC (25), because C16 has a higher thermal stability than IP6. To the contrary, similarly to C13, C14, and C15, the C16 level arises when the N3 is reactivated close to the implanted Cl profile. For the same reason, it can be thought that Cl can participate in the microscopic structure of C16.

In order to find out more evidence on the nature of the C12, C13, C14, C15, and C16 levels, we analyzed the depth profiles of these traps and compared them with the Cl-implanted distribution obtained by Monte-Carlo simulations. These levels were detected in n- and p-type samples that underwent the last annealing stage at 1800°C, and depth profiles measurements were performed by changing the reverse bias voltage up to ±6 V. As it is shown in Fig. 3, the concentration of the C12 trap is found outside the implanted region, at a depth of 0.65 μm from the epilayer surface and has rather uniform depth distribution. The lack of a localized depth distribution close to the implanted Cl profile rules out the possible involvement of Cl in the microscopic nature of C12 and favors the identification of this defect as the D-center. The depth profiles of C13, C14, C15, and C16 display similar features: The concentrations of these traps show a rather steep increase of concentration for

decreasing depth, in contrast to the more gradual increase of the \( \text{EH}_{6/7} \) and \( \text{IM8} \) depth distributions. Analogously to \( \text{Cl}2 \), the depth profile of \( \text{Cl}3 \) does not show a narrow and localized distribution close to the \( \text{Cl} \) implantation peak; therefore, also for this trap, it can be concluded that the involvement of \( \text{Cl} \) may be unlikely.

Regarding the \( \text{Cl}4 \), \( \text{Cl}5 \), and \( \text{Cl}6 \) levels two scenarios are possible. First, the extrapolation of these depth profiles, toward the surface, may yield very high defect concentration for a depth \( \leq 0.6 \) \( \mu \)m. This rules out the possibility of \( \text{Cl} \) involvement but would explain why, even after heat treatments up to 1800 \( ^\circ \)C, no reactivation of either \( N_d \) or \( N_i \) has been achieved. Second, although the measurements are not feasible for a depth \( \leq 0.6 \) \( \mu \)m, the depth profiles of \( \text{Cl}4 \), \( \text{Cl}5 \), and \( \text{Cl}6 \) may have a localized distribution around the maximum of the implantation peak, and for this reason, the involvement of \( \text{Cl} \) would be possible. If this would be the case, two different charge states of the \( \text{Cl}_i \) complex have very close to the energy level position of \( \text{Cl}4 \) and \( \text{Cl}5 \) while a \( \text{Cl} \) interstitial (\( \text{Ci} \)) level was predicted at \( E_V + 0.96 \) eV, very similar to the energy position of the \( \text{Cl}6 \) level.

IV. CONCLUSIONS

Twelve deep levels were detected in either \( n \)- or \( p \)-type 4H-SiC implanted with 700 keV \( \text{Cl} \). Of these, four levels are found to arise after \( \text{Cl} \) implantation and labeled \( \text{Cl}3 \), \( \text{Cl}4 \), \( \text{Cl}5 \) (in \( n \)-type 4H-SiC), and \( \text{Cl}6 \) (in \( p \)-type). The involvement of \( \text{Cl} \) in the microscopic nature of these defects was discussed in detail in the light of previous theoretical studies and of the results of a depth profile analysis. We conclude that the \( \text{Cl} \) involvement is unlikely for the \( \text{Cl}3 \) level, whose nature could be linked to the presence of implantation related defects, but it may be more plausible for the \( \text{Cl}4 \), \( \text{Cl}5 \), and \( \text{Cl}6 \) levels.
