(Received 25 September 2012; revised manuscript received 19 February 2013; published 28 February 2013)

We report the \( ^{121}/^{123}\text{Sb-NMR/nuclear quadrupole resonance (NQR)} \) measurements on the superconductor \( \text{BaTi}_2\text{Sb}_2\text{O} \) with a two-dimensional Ti\(_2\)O square-net layer formed with Ti\(^{3+}\) (3d\(^1\)). NQR measurements revealed that the in-plane four-fold symmetry is broken at the Sb site below \( T_A \sim 40 \text{ K} \), without an internal field appearing at the Sb site. These exclude a spin-density wave (SDW)/charge density wave (CDW) ordering with incommensurate correlations, but can be understood with the commensurate CDW ordering at \( T_A \). The spin-lattice relaxation rate \( 1/T_1 \), measured at the four-fold symmetry breaking site, decreases below superconducting (SC) transition temperature \( T_c \), indicative of the microscopic coexistence of superconductivity and the CDW/SDW phase below \( T_A \). Furthermore, \( 1/T_1 \) of \( ^{121}\text{Sb-NQR} \) shows a coherence peak just below \( T_c \) and decreases exponentially at low temperatures. These results are in sharp contrast with those in cuprate and iron-based superconductors, and strongly suggest that its SC symmetry is classified to an ordinary \( s\)-wave state.

DOI: 10.1103/PhysRevB.87.060510 PACS number(s): 71.20.Be, 74.25.–q, 75.25.Dk, 76.60.–k

I. INTRODUCTION

After the discovery of high-\( T_c \) cuprate superconductors, many efforts have been made to synthesize new high-\( T_c \) superconductors. These activities have brought us the discovery of various unconventional superconductors, [e.g., \( \text{Sr}_3\text{RuO}_4 \), \( ^{123}\text{NaCoO}_2 \), \( ^{15}\text{H}_2\text{O} \), \( ^{75}\text{LaFeAs}(\text{O}_1- \text{F}_x) \)] so far. It is quite interesting that all these superconductors possess a two-dimensional layered structure and are located near the magnetic instability, both of which are regarded as essential ingredients of high-\( T_c \) superconductors. Actually \( T_c \) in a quasi-two-dimensional system is theoretically shown to be higher than in a three-dimensional system, since magnetic fluctuation is generally enhanced by low dimensionality.

Quite recently, it was reported that two-dimensional oxyantimonide \( \text{BaTi}_2\text{Sb}_2\text{O} \) shows a superconducting (SC) transition at \( T_c \sim 1 \text{ K} \). \( ^{121}\text{Sb-NMR/nuclear quadrupole resonance (NQR)} \) measurements revealed that the in-plane four-fold symmetry is broken at the Sb site below \( T_A \sim 40 \text{ K} \), without an internal field appearing at the Sb site. These exclude a spin-density wave (SDW)/charge density wave (CDW) ordering with incommensurate correlations, but can be understood with the commensurate CDW ordering at \( T_A \). The spin-lattice relaxation rate \( 1/T_1 \), measured at the four-fold symmetry breaking site, decreases below superconducting (SC) transition temperature \( T_c \), indicative of the microscopic coexistence of superconductivity and the CDW/SDW phase below \( T_A \). Furthermore, \( 1/T_1 \) of \( ^{121}\text{Sb-NQR} \) shows a coherence peak just below \( T_c \) and decreases exponentially at low temperatures. These results are in sharp contrast with those in cuprate and iron-based superconductors, and strongly suggest that its SC symmetry is classified to an ordinary \( s\)-wave state.

II. EXPERIMENTAL

\( \text{BaTi}_2\text{Sb}_2\text{O} \) was synthesized by the conventional solid state reaction method. NMR measurements are performed in the same batch as magnetic susceptibility and resistivity measurements. To prevent sample degradation by air and/or moisture, the polycrystalline sample was mixed with stycast 1266, and the mixture was solidified with random crystal orientation. All procedures were done in a glove box filled with \( \text{N}_2 \). \( T_c \approx 0.95 \text{ K} \) of the sample was determined from the diamagnetic shielding signal, which is consistent with the previous report. No reaction was recognized between the sample and stycast, since \( T_c \) and \( T_A \) are unchanged during our measurements.

III. RESULTS AND DISCUSSION

Figure 2 shows the \( ^{121}/^{123}\text{Sb-NQR} \) spectra, which were obtained by frequency-swept method at 45 K (\( > T_A \)) and 4.2 K (\( < T_A \)). There are two isotopes of Sb nuclei, properties of which are summarized in Table I. When \( I \geq 1 \), a nucleus has an electric quadrupole moment \( Q \) as well as a magnetic dipole moment, and thus the degeneracy of nuclear-energy levels is lifted even at zero magnetic field due to the interaction between \( Q \) and the electric field gradient (EFG). This interaction is described as

\[
\mathcal{H}_Q = \frac{v_{zz}}{2} \left\{ 3I_I^2 - I^2 \right\} + I\eta(I^2 + I_z^2),
\]

where \( v_{zz} \) is the quadrupole frequency along the principal axis (\( c \)-axis) of the EFG, and is defined as \( v_{zz} = 3e^2qQ/2I(2I - 1) \) with \( eq = V_{zz} \) and \( \eta \) is an asymmetry parameter of the EFG expressed as \( V_{zz} \equiv V_{yy} = V_{xx} \). The EFG along the \( \alpha \) direction (\( \alpha = x, y, z \)). When \( ^{121}\text{Sb} \) (\(^{123}\text{Sb}\)) is in the presence of the EFG, the degenerate six (eight) nuclear-spin states are split into three (four) energy levels, yielding two (three) resonance frequencies as shown in Fig. 2. The quadrupole parameters \( v_{zz} \) and \( \eta \) for each Sb nuclei are estimated from the comparison between the observed...
$^{121/123}$Sb-NQR spectra and calculated resonance frequencies obtained from the diagonalization of Eq. (1) as shown in Fig. 2. Field-swept NMR spectra can be consistently fit by the simulation calculated with the same quadrupole parameters as shown in Fig. 4, indicative of the validity of the NQR analysis.

Reflecting the four-fold symmetry of the crystal structure, $\eta$ is zero at 45 K, while the NQR spectrum is gradually shifted below 40 K. $T$ dependence of the resonance frequencies arising from the $\pm 1/2 \leftrightarrow \pm 3/2$ ($v_1$) and $\pm 3/2 \leftrightarrow \pm 5/2$ ($v_2$) transition of $^{123}$Sb is shown in Fig. 3(a). In the case of $I = 7/2$, NQR frequencies from each transition can be described as

$$v_1 = v_{zz} \left(1 + \frac{109}{30} \eta^2\right), \quad v_2 = 2v_{zz} \left(1 - \frac{17}{30} \eta^2\right)$$

within the second-order perturbation of $\eta$ in $P_{zz}$. Above 40 K, the experimental result shows the relation $v_2/v_1 \approx 2(1 - \frac{21}{28} \eta^2) \approx 2$ within the experimental error, but at 4.2 K, the result shows $v_2/v_1 \approx 1.9$, which is evidence of finite $\eta$. From the above resonance frequencies, we derived $T$ variation of $\eta$ and $v_{zz}$, which is shown in Fig. 3(b) and the inset, respectively. The $T$ dependence of $v_{zz}$ is consistent with that in the lattice parameters,8 indicative of the validity of the estimation. The spectra below $T_A$ can be interpreted by the change of $v_{zz}$ and the finite $\eta$ without an internal field appearing at the Sb site. This indicates the breaking of the in-plane four-fold symmetry at the Sb site at low temperatures. The $\eta$ changes continuously below 40 K and no clear hysteresis is observed, showing the transition at $T_A$ to be second order.

Hence, we focus on the $T$ dependence of low-energy spin dynamics probed with $1/T_1$ measurements at the Sb site. Figure 5 shows the $T$ dependence of $1/T_1$ of $^{121/123}$Sb-NQR spectra, which were obtained by frequency-swept method at (a) 45 K and (b) 4.2 K. From the observed $^{121/123}$Sb-NQR spectra, the quadrupole parameters for the Sb nuclei were evaluated as shown in the figure. The broken curves are the simulation of NQR spectra using the estimated quadrupole parameters. The asymmetry parameter $\eta$ becomes finite at 42 K, indicative of the in-plane four-fold symmetry breaking at the Sb site. Linewidths of NQR spectra can be explained by only the electric field gradient distribution, indicative of the absence of internal magnetic field at the Sb site.

Next, we focus on the $T$ dependence of low-energy spin dynamics probed with $1/T_1$ measurements at the Sb site. Figure 5 shows the $T$ dependence of $1/T_1$ of $^{121/123}$Sb-NQR spectra, which were obtained by frequency-swept method at (a) 45 K and (b) 4.2 K. From the observed $^{121/123}$Sb-NQR spectra, the quadrupole parameters for the Sb nuclei were evaluated as shown in the figure. The broken curves are the simulation of NQR spectra using the estimated quadrupole parameters. The asymmetry parameter $\eta$ becomes finite at 42 K, indicative of the in-plane four-fold symmetry breaking at the Sb site. Linewidths of NQR spectra can be explained by only the electric field gradient distribution, indicative of the absence of internal magnetic field at the Sb site.

Next, we focus on the $T$ dependence of low-energy spin dynamics probed with $1/T_1$ measurements at the Sb site. Figure 5 shows the $T$ dependence of $1/T_1$ of $^{121/123}$Sb-NQR spectra, which were obtained by frequency-swept method at (a) 45 K and (b) 4.2 K. From the observed $^{121/123}$Sb-NQR spectra, the quadrupole parameters for the Sb nuclei were evaluated as shown in the figure. The broken curves are the simulation of NQR spectra using the estimated quadrupole parameters. The asymmetry parameter $\eta$ becomes finite at 42 K, indicative of the in-plane four-fold symmetry breaking at the Sb site. Linewidths of NQR spectra can be explained by only the electric field gradient distribution, indicative of the absence of internal magnetic field at the Sb site.

and (b) \( \eta \) in lattice parameters, indicative of the validity of the NQR analysis. The quadrupole parameters \( \nu_{zz} \) and \( \eta \) are estimated from these resonance frequencies. The \( \eta \) changes continuously below \( \Delta m \approx 40 \) K and no appreciable hysteresis is observed, indicating that this phase transition is second order. The broken line is a guide to the eyes. The schematic image of the CDW state, which is one of the promising phase transition is second order. The broken line is a guide to the eyes. In general, an NMR/NQR spin lattice relaxation process is dominated in the whole temperature range and \( T_{\text{recovers the FL state}} \). Upon further cooling, the resistivity and susceptibility measurements, although a tetragonality is maintained below \( T_{\text{A}} \). On the other hand, fluctuations of EFG cause electric-quadrupole relaxations between the nuclear spin levels of the Ti site represents the difference of the charge densities of Ti. In the case of magnetic channel, fluctuations of local magnetic fields at a nuclear site cause magnetic relaxations between the nuclear spin levels of the Ti site represents the difference of the charge densities of Ti. In general, an NMR/NQR spin lattice relaxation process is dominated in the whole temperature range and magnetic fluctuations enhance toward \( \Delta m \approx 40 \) K.

\[
\frac{121I_{M}^{-1}}{123I_{M}^{-1}} = \left( \frac{10.189}{5.5175} \right)^2 = 3.41
\]

is estimated from Table I.

On the other hand, fluctuations of EFG cause electric-quadrupole relaxations between the nuclear spin levels of \( \Delta m = \pm 1 \) and \( \Delta m = \pm 2 \). In this case, the electric-quadrupole relaxation rate is related to the quadrupole moment \( Q \) by \( T_{1M}^{-1} \sim 3Q/Q^{2}/(10(2I - 1)I^2) \). From obtained \( \nu_{zz} \equiv 3\nu_{zz}^{2}Q/2(2I - 1) \), the ratio of \( 121I_{Q}/123I_{Q} \) can be estimated as

\[
\frac{121I_{Q}}{123I_{Q}} = \frac{2}{3} \cdot \frac{5}{3} (2 \cdot \frac{5}{3} - 1) \cdot \frac{121}{123} \nu_{zz} \simeq 0.80.
\]

Then,

\[
\frac{121T_{1M}^{-1}}{123T_{1M}^{-1}} \approx \left\{ \frac{3(2 \cdot 3 + 1)I^2}{10(2I - 1)I^2} \right\} \left( \frac{121I_{Q}}{123I_{Q}} \right)^2 \approx 2.34 \times 0.80^2 = 1.50
\]

is calculated. From the NQR measurements, the ratio of \( 121T_{1M}^{-1}/123T_{1M}^{-1} \) is \( \sim 3 \), indicating that the magnetic relaxation process is dominated in the whole temperature range and magnetic fluctuations enhance toward \( \Delta m \approx 40 \) K.
the $^{121/123}\text{Sb-NMR/NQR}$ spectra at low temperatures revealed that the in-plane four-fold symmetry is broken at the Sb site below $T_A \sim 40$ K without the internal field appearing at the Sb site. The absence of an internal field excludes the SDW ordering with an incommensurate correlation, since otherwise internal fields should appear at the Sb site, resulting in resonance peaks, particularly those arising from the transition between $m = \pm 1/2$ and $\pm 3/2$, that are split or broadened.

 Alternatively, the change of the NQR spectra below $T_A$ can be understood by the occurrence of the commensurate CDW ordering. When a CDW transition occurs, there appear several Ti sites with different charge densities in most cases. However, the shift of the $^{121/123}\text{Sb NQR}$ peak without splitting nor appreciable broadening below $T_A$ gives a strong constraint and indicates that charge densities at the Ti sites should have a commensurate correlation, since there would be several Sb sites induced below $T_A$ if a CDW ordering possesses an incommensurate correlation. The different charge densities at the Ti sites, e.g., the Ti configuration shown in Fig. 3(b), break the in-plane four-fold symmetry at the Sb site although a tetragonality is maintained below $T_A$. The charge difference at the Ti site is considered to be small since the change of the DOS probed with $1/T_1 T$ and the kink of the resistivity are very small below $T_A$. However, the possibility of the magnetic ordering together with the CDW ordering at $T_A$ would not be ruled out, since we cannot exclude commensurate magnetic ordering with a specific relationship between magnetic correlations and ordered moment direction [e.g., internal fields are canceled out at the Sb site when magnetic correlations are checkerboard $(\pi,\pi)$ and ordered moments direct to the $c$ axis, even if the off-diagonal hyperfine fields are taken into account$^{[15,16]}$. To exclude the possibility of magnetic ordering, NMR/NQR measurements at the Ti site and/or neutron scattering measurements are crucial. It should be noted that magnetic fluctuations are enhanced toward $T_A$. In a well-known $2H$-NbSe$_2$, where superconductivity ($T_c \sim 7$ K) occurs below the CDW transition at $T_{\text{CDW}} \sim 35$ K, no anomaly was observed in $1/T_1$ at $T_{\text{CDW}}$, however the similar anomaly of $1/T_1$ as in BaTi$_2$Sb$_2$O was observed in Lu$_4$Ir$_4$Si$_{10}$ at $T_{\text{CDW}}$. Since the relationship between charge and magnetic degree of freedom has not been well understood, BaTi$_2$Sb$_2$O might be one of the suitable systems to investigate a correlation between charge and spin dynamics.

Next, we discuss the $1/T_1$ in the SC state. $1/T_1$ of $^{121}\text{Sb-NQR}$ slightly decreases below 1.5 K, where a small Meissner signal appears, but $1/T_1$ shows a tiny coherence peak just below $T_c \simeq 0.95$ K, where the sharp Meissner signal is observed, and then rapidly decreases at low temperatures as shown in Fig. 6. $T$ dependence of $1/T_1$ far below $T_c$ is much steeper than $T^3$ dependence, but $T_1$ follows an exponential $T$ dependence down to 0.3 K, as shown by an Arrhenius plot in the inset of (b). These are in sharp contrast with $T$ dependence in cuprate$^{[18,19]}$ and iron-based superconductors.$^{[18,19]}$

From the slope of the plot, the magnitude of the SC gap is estimated to be $2\Delta/k_B T_c = 4.4$, and actually the observed $1/T_1$ in the SC state can be fit consistently by an $s$-wave full gap model with $2\Delta/k_B T_c = 4.4$ and $\delta/\Delta = 0.5$, where $\delta$ is the broadening parameter of the singularity in the SC DOS. Absence of the residual DOS in the SC state is also consistent with an $s$-wave model, since residual DOS suggested by the Korringa behavior far below $T_c$ is easily introduced by disorder and/or a tiny amount of impurities in unconventional superconductors.$^{[20,21]}$ Since the present NQR measurements were done in an “early-stage” polycrystalline sample, the full-gap $s$-wave state would be the most possible SC gap state in BaTi$_2$Sb$_2$O.

IV. SUMMARY

In summary, the NQR asymmetric parameter $\eta$ becomes finite below $T_A \simeq 40$ K, indicative of the breaking of the in-plane four-fold symmetry at the Sb site without an internal field appearing at the Sb site. The variation of the NQR spectra below $T_A$ can be understood by the occurrence of the commensurate CDW transition. $1/T_1$ below $T_A$ shows a further anomaly below $T_c$ due to the opening of the SC gap, indicative of the coexistence of superconductivity and the anomaly occurring at $T_A$. In the SC state, $1/T_1$ shows a coherence peak just below $T_c$ and exponentially decreases at low temperatures, which strongly suggests that the SC symmetry of BaTi$_2$Sb$_2$O is an $s$ wave with finite SC gap.
