1 **ABSTRACT**

2 *Objective.* To elucidate changes in endothelial function throughout the gestational period in  
3 normal pregnancy and its relationship with plasma sFlt-1 levels. *Methods.* Endothelial  
4 function was evaluated by reactive hyperemia index (RHI) using Endo-PAT2000 and plasma  
5 sFlt-1 levels were measured simultaneously by ELISA. *Results.* RHI gradually deteriorated  
6 with increasing the gestational age. Plasma sFlt-1 levels exhibited a gradual increase at late  
7 pregnancy and were inversely correlated with RHI. *Conclusion.* Maternal endothelial function  
8 gradually deteriorates with increasing gestational age and there is an inverse correlation  
9 between endothelial function and plasma sFlt-1 levels in normal pregnancy.

## 1 INTRODUCTION

2 In normal pregnancy, blood volume and cardiac output increase as pregnancy proceeds. By  
3 contrast, blood pressure gradually decreases slightly toward mid-pregnancy and then slowly  
4 increases toward the term (1). It is assumed that this discrepancy is due at least in part to  
5 alterations in endothelial function based on reductions in systemic vascular resistance by  
6 nitric oxide (NO) (2). In preeclampsia (PE), it is acknowledged that poor placentation in early  
7 pregnancy causes placental hypoperfusion with subsequent maternal endothelial dysfunction.  
8 The endothelial dysfunction in various tissues is implicated in symptoms such as hypertension,  
9 proteinuria, tissue oedema, cerebral haemorrhage, and so on (3). Therefore an assessment of  
10 endothelial function might be useful for prediction, prevention, and curative strategies for PE  
11 patients. However, it is still controversial whether endothelial function changes throughout  
12 normal pregnancy (4-8).

13 Endothelial function includes vasodilatory, anti-coagulant, anti-inflammatory and  
14 vascular permeability activities. It is thought that vascular homeostasis is well maintained (9)  
15 and NO and vascular endothelial growth factor (VEGF) play central roles in these  
16 mechanisms. Soluble fms-like tyrosine kinase-1 (sFlt-1) has been implicated in the symptoms  
17 of PE. It is a soluble type of VEGFR-1 and competes with VEGF for binding to VEGF  
18 receptors. Rats over-expressing sFlt-1 show similar clinical features of PE (10). In PE patients,  
19 increased circulating sFlt-1 levels have been reported compared with normal pregnant women

1 (10, 11) and the importance of elevated sFlt-1 levels has been discussed in relation to  
2 endothelial dysfunction (12). However, the relationship between circulating sFlt-1 levels and  
3 endothelial function in normal pregnancy remains unclear.

4 To assess endothelial function, flow-mediated dilation (FMD) of the brachial artery  
5 during reactive hyperemia (RH) has been introduced. Though FMD is a gold standard for  
6 non-invasive assessment of endothelial function, the measurement of FMD has a potential  
7 limitation regarding its intra-and inter-operator reproducibility (13). To overcome this  
8 problem, peripheral arterial tonometry (PAT) has recently been developed. The Endo-  
9 PAT2000 system (Itamar Medical, Caesarea, Israel) does not require the operator to have the  
10 training and specialized skill needed when using ultrasonography. Corretti reported that PAT  
11 method is significantly correlated with FMD ( $p < 0.0001$ ) (13). In comparing PAT with FMD,  
12 Carty measured PAT and FMD in the same pregnant women. In the result, it was showed that  
13 both parameters compared favorably (14). The data reflect arterial tone alterations in the  
14 peripheral microvascular bed and can be digitalized and read as reactive hyperemia index  
15 (RHI). The influence of the autonomic nervous system can be eliminated by measuring the  
16 contralateral arm as a control. Thus, the PAT method might be superior to FMD in terms of  
17 convenience, quantitation, and reproducibility (15). RHI in patients with coronary endothelial  
18 dysfunction was reported to be relatively lower (16). Another study demonstrated that  
19 administration of L-NAME, known as an inhibitor of eNOS, reduced RHI, implicating NO-

1 dependent endothelial function (17). In addition, Aragonés reported that elevated levels of sE-  
2 selectin, a biomarker for endothelial dysfunction, were associated with lower RHI (18).  
3 However there have been few articles so far investigating the role of endothelial function  
4 using RHI in PE patients. One report presented reduced RHI in patients with PE compared  
5 with normal pregnant women around 32 weeks of gestation (19). Recently, Carty et al.  
6 demonstrated that RHI in pregnant women at 28 weeks was significantly lower than that at 16  
7 weeks (14), but they just focused on the predictive value of the onset of PE and concluded  
8 that it failed for that purpose.

9       Here we report a prospective study of monitoring maternal RHI to evaluate endothelial  
10 function throughout the normal gestational period using the Endo-PAT system. We also  
11 measured endothelial function and circulating sFlt-1 levels in non-pregnant women,  
12 preeclamptic patients and pregnant women who develop PE later. Because the significance of  
13 increased sFlt-1 levels in normal late gestation has not been clarified, we measured plasma  
14 sFlt-1 levels in all subjects and evaluated the relationship between RHI and plasma sFlt-1  
15 levels. The aim of this study was to elucidate alterations in endothelial function using the PAT  
16 system and its correlation to plasma sFlt-1 levels throughout the normal gestational period as  
17 well as the process of PE.

18

## 1 **MATERIALS AND METHODS**

### 2 **Study Population**

3 All pregnant women consulting our department at Kyoto University Hospital between  
4 March 2011 and March 2012 were considered for enrolment. Complicated cases with chronic  
5 hypertension, diabetes mellitus, chronic kidney disease, autoimmune diseases like systemic  
6 lupus erythematosus and respiratory diseases were excluded. Over eighty percent of eligible  
7 pregnant women were enrolled in the present study. Age-matched, apparently healthy non-  
8 pregnant women were also enrolled. In addition, we enrolled 7 patients who had already  
9 developed symptoms of PE and had been treated with antihypertensive drugs. The protocol  
10 was approved by the institutional ethics committee of Kyoto University Graduate School of  
11 Medicine. Written informed consent was obtained from all subjects.

12

### 13 **Measurement of Endothelial Function**

14 PAT is a new technique to non-invasively assess endothelial function. It comprises  
15 finger probes to evaluate digital volume changes accompanied by pulse waves (20). We used  
16 the Endo-PAT2000 system to evaluate endothelial function. All participants were asked to  
17 abstain from caffeine, alcohol and cigarette smoking for at least 24 hours before the  
18 examination. The PAT study was conducted at least 3 hours after a light meal. A temperature

1 controlled (23 to 26 °C), quiet and dark room was reserved for the examination. A blood  
2 pressure cuff was placed on one upper arm and a probe was placed on the tip of the index  
3 finger; the probe sensor on the contralateral arm served as a control. Following approximately  
4 15 min of resting in a supine position on the bed, the baseline digital volume signals were  
5 recorded for 5 min, then the blood pressure cuff was inflated to 200 mmHg to occlude the  
6 brachial artery and the pressure was maintained for 5 min. The cuff was then released to  
7 induce RH and the reaction was recorded for 5 min. The analytical method of calculating RHI  
8 was as follows. The RHI reflects the ratio of the alteration in the amplitude from 90 to 150  
9 seconds after the cuff is released (occluded arm –A; non-occluded arm - C) divided by the  
10 average amplitude of the signal from 170 to 20 seconds before the cuff is inflated (occluded  
11 arm - B; non-occluded arm - D). This value was calculated using the formula:  $RHI = (A/B) /$   
12  $(C/D)$ . The RHI data were digitally analysed using the Endo-PAT2000 software version 3.3.2  
13 (Itamar Medical). Each pregnant woman underwent this test 1 to 3 times at intervals of longer  
14 than one month apart.

15

### 16 **Plasma Sampling and Measurement of sFlt-1 Levels**

17 Plasma samples were collected from all pregnant women who participated in this study  
18 and age-matched non-pregnant women at the same day as the PAT examination. The blood  
19 was collected into tubes containing EDTA and the plasma was then separated by

1 centrifugation at 3000 rpm for 30 min. The supernatants were stored at -20 °C until analysis.  
2 Plasma sFlt-1 levels were measured using a human sVEGFR1/Flt-1 enzyme-linked  
3 immunosorbent assay (ELISA) kit (R&D Systems, Minneapolis, MN) in duplicate according  
4 to the manufacturer's protocol. Inter-assay and intra-assay coefficients of variation were 5.5–  
5 9.8 % and 2.6–3.8 %, respectively.

6

### 7 **Diagnosis of PE**

8 PE was defined as the new onset of hypertension and proteinuria after 20 weeks of  
9 gestation. Hypertension was defined as a systolic blood pressure  $\geq$  140 mmHg or diastolic  
10 blood pressure  $\geq$  90 mmHg on two measurements at least 4 hours apart, and proteinuria as  $\geq$   
11 300 mg/day (21). In Japan, it is defined that late-onset preeclampsia develops at or after 32  
12 weeks of gestation.

13

### 14 **Statistical Analysis**

15 The results of normally distributed continuous variables are expressed as the mean  $\pm$   
16 SEM (range), while those with skewed distribution are expressed as the median value with  
17 [interquartile range]. Continuous variables were analysed by the Wilcoxon *t* test, Mann-  
18 Whitney *U* test and Kruskal-Wallis *H* test, as appropriate. Pearson's correlation coefficient  
19 was used to evaluate possible associations. A *p* value of  $< 0.05$  denoted statistical significance.

1 Statistical analyses were performed using Prism 3.0 (GraphPad Software, La Jolla, CA).

2

### 3 **RESULTS**

#### 4 **Patient Characteristics**

5 The information collected on the study population is shown in Table 1. Three of 29  
6 pregnant women developed PE. Body mass indexes were significantly higher in the normal  
7 control pregnant women than in the non-pregnant women. In 7 PE patients, systolic and  
8 diastolic blood pressures were not high due to antihypertensive treatment and the median time  
9 of measuring RHI was 32 [31.5–34] weeks of gestation. The average of systolic blood  
10 pressure was  $161 \pm 5$  mmHg, and the diastolic blood pressure was  $95 \pm 4$  mmHg, when PE  
11 patients were diagnosed at first time. RHI measurements in PE patients were performed 4  
12 [2.5-5.5] days after start of the treatment. Gestational age at delivery was earlier in the PE  
13 group than in normal pregnant women. Neonatal weight was also lighter in the PE patients  
14 than in normal pregnant women and patients with late PE development.

15

#### 16 **Alterations of RHI in Normal Pregnancy**

17 The RHI gradually decreased throughout gestation in normal pregnant women (Figure  
18 1A). The RHI in weeks 20–31 and over 32 weeks of gestation was significantly lower than  
19 that prior to 20 weeks of gestation. However, there was no significant difference in RHI

1 between non-pregnant women and pregnant women under 19 weeks of gestation (Figure 1B).

2

### 3 **Relation of RHI to Plasma sFlt-1 Levels**

4 Plasma sFlt-1 levels gradually increased throughout gestation in normal pregnant women  
5 (Figure 2A). They were higher in pregnant women over 32 weeks of gestation than those at  
6 earlier periods of gestation (Figure 2B). The RHI was inversely correlated with plasma sFlt-1  
7 levels ( $p = 0.0074$ ) for all 56 measurements in normal pregnant women (Figure 3).

8 Figure 4 shows comparisons of RHI (A) and plasma sFlt-1 levels (B) during 3  
9 gestational periods ( $\leq 19$  weeks, 20–31 weeks,  $\geq 32$  weeks). Nine normal pregnant women  
10 were given repeat measurements in each gestational period. The RHI in pregnant women over  
11 32 weeks of gestation was significantly lower than in those under 19 weeks of gestation. In  
12 contrast, plasma sFlt-1 levels in pregnant women over 32 weeks of gestation were  
13 significantly higher than those less than 20 weeks or between 20 and 31 weeks of gestation.

14

### 15 **RHI and Plasma sFlt-1 Levels in PE and Late PE Development Patients**

16 The RHI in PE patients was significantly higher than in normal pregnant women at the  
17 same gestational stage (31–36 weeks) (Figure 5A). On the other hand, plasma sFlt-1 levels  
18 showed over a 3-fold increase in PE patients ( $p = 0.004$ ) (Figure 5B). RHI was measured in  
19 two PE patients after vaginal delivery. The RHI in one case was increased (1.58 to 1.86) nine

1 days after the delivery. In another case, it was similarly increased (1.65 to 1.84) twelve days  
2 after the delivery.

3 Three of 29 pregnant women developed PE in this study. The RHI and plasma sFlt-1  
4 levels were measured at 10–15 weeks and 29–32 weeks of gestation, before the onset of PE in  
5 these 3 patients. Both RHI and plasma sFlt-1 levels were no different at 10–15 weeks of  
6 gestation. While RHI was still comparable at 29–32 weeks of gestation, plasma sFlt-1 levels  
7 were slightly higher in patients with late PE development.

8

## 9 **COMMENT**

10 Salient findings of the present study were as follows: (1) Endothelial function evaluated by  
11 PAT gradually deteriorated with the progression of gestational age in normal pregnant women.  
12 (2) Plasma sFlt-1 levels exhibited a gradual increase late in pregnancy and were inversely  
13 correlated with the RHI. (3) In the PE patients, RHI, an index of endothelial function, showed  
14 a higher value in the presence of higher plasma sFlt-1 levels compared with normal pregnant  
15 women at similar gestational ages.

16 In the present study, we examined endothelial function by PAT in more detail and  
17 demonstrated for the first time that RHI gradually decreases with increasing gestational age.  
18 While some reports have claimed endothelial function ameliorates, others reported a decline  
19 throughout normal pregnancy (4-8). These earlier studies utilized FMD of the brachial artery

1 as a method of evaluating endothelial function. Lack of good reproducibility in the FMD  
2 technique may explain, at least in part, inconsistent results in earlier studies. On the other  
3 hand, the PAT technique provides more accurate information on endothelial function  
4 regardless of the operator's skill and the autonomic nervous system activity of the examinee.  
5 (15). Carty et al. has used PAT and reported that RHI at 28 weeks of normal pregnancy was  
6 significantly lower than at 16 weeks (14). In the present study, we examined endothelial  
7 function by PAT in more detail and demonstrated that RHI gradually decreases with  
8 increasing gestational age, consistent with recent reports (14). Therefore we conclude that  
9 endothelial function was deteriorating even in normal pregnancy.

10       Although it has been already shown that sFlt-1 levels are increasing during gestation, we  
11 first that demonstrated that plasma sFlt-1 levels and RHI were inversely correlated. Until now,  
12 there is no study showing a correlation between endothelial function and plasma sFlt-1 levels  
13 in normal pregnant women. As one of the reasons, we think that data analysis by FMD  
14 method may have some difficulty, in terms of convenience, quantitation, and reproducibility.  
15 Increased plasma sFlt-1 are suggested to neutralize VEGF and attenuate the beneficial effect  
16 of VEGF on endothelial function in PE patients, though the relation between plasma sFlt-1  
17 levels and endothelial function remains unclear in normal pregnancy. From the current results,  
18 it can be speculated that the elevation of plasma sFlt-1 levels in the late pregnancy may cause  
19 endothelial dysfunction. However, it is unknown whether elevated sFlt-1 influences

1 endothelial function directly and further studies will be needed to elucidate this relationship.

2       In our findings, the RHI in PE patients was relatively high. Markedly increased plasma  
3 sFlt-1 levels in PE patients strongly suggest poorer endothelial function (22). It has already  
4 been demonstrated that FMD is reduced in PE patients (23-25). Therefore our results appear  
5 curious and must be interpreted with caution. The following two reasons may account for  
6 about the cause of dissociation of this result. First, all PE patients in our study were medicated  
7 with calcium blocker and/or magnesium sulfate, which potentially improved their endothelial  
8 function. Second, there is a report that RH itself is slightly pressure-dependent ( $\beta = 0.007$ ,  $p$   
9  $< 0.001$ ) (26). Generally, it is thought that endothelial dysfunction leads to hypertension and  
10 arteriosclerosis. However, in the presence of high blood pressure, an evaluation of endothelial  
11 function by PAT may be influenced by blood pressure. In PAT analysis, in contrast to our  
12 result showing increased RHI, Yinon et al. (19) have reported decreased RHI in a study in PE  
13 patients in which cases of relatively early onset were enrolled more frequently than in ours. It  
14 is probable that markedly depressed endothelial function leads to a lower RHI despite the  
15 presence of high blood pressure. Thus the relatively high RHI values in PE patients might be  
16 due to their higher blood pressure level or to drugs, though this needs to be further elucidated.

17       The limitation to the present study was that the number of patients who developed PE at  
18 the later gestational stage was too small for us to be able to assess whether endothelial  
19 function in the early stages of gestation is able to predict the onset of PE.

1           Angiogenic factors, including VEGF, in maternal vessels are important for maintaining  
2 normal endothelial function. In PE patients, the normal balance between angiogenesis and  
3 anti-angiogenesis has been compromised by circulating factors, including sFlt-1 and others,  
4 from the placenta. Up to the present, there is no method to evaluate endothelial function that  
5 combines non-invasiveness with convenience, quantitation and reproducibility. Although  
6 further study must be done regarding the influence of blood pressure levels, it appears that  
7 PAT will become a useful tool to assess maternal endothelial function hereafter. We believe  
8 research into predicting or understanding the pathogenesis of PE might progress if more  
9 measurements of anti-angiogenic or angiogenic factors in maternal blood can be added to the  
10 accumulating data on this topic.

11           In conclusion, we here evaluated maternal endothelial function using the novel  
12 methodology of the Endo-PAT2000 system and simultaneously measured plasma sFlt-1 levels  
13 in pregnant women. Our investigation revealed that maternal endothelial function gradually  
14 deteriorated while plasma sFlt-1 levels increased in inverse correlation with gestational age in  
15 normal pregnancy. Anti-angiogenic or angiogenic factor profiling combining with RHI will  
16 be valuable for predicting and understanding the pathogenesis of PE.

**Table1:** Clinical characteristics and pregnancy outcomes in study subjects.

	<b>Non-pregnant women</b>	<b>Normal pregnant women</b>	<b>Late PE development</b>	<b>PE</b>
Subjects (n)	9	26	3	7
Total number of measurement (n)	9	56	6	7
Age (years)	32.0 ± 2.4 (21-45)	33.3 ± 1.0 (25-41)	36.0 ± 2.0 (34-40)	34.6 ± 0.6 (24-36)
Primipara (n)	(-)	23/26	1/3	5/7
<b>Physical findings at the first time of measurement:</b>				
Body mass index (kg/m <sup>2</sup> )	19.3 ± 0.5 (16.6-21.4)	24.1 ± 0.9 <sup>a</sup> (18.4-37.9)	21.7 ± 1.4 (18.8-23.1)	26.4 ± 1.4 <sup>a</sup> (23.1-32.0)
Systolic blood pressure (mmHg)	110 ± 2 (98-120)	108 ± 2 (90-133)	108 ± 6 (100-119)	136 ± 5 <sup>a, b</sup> (120-150)
Diastolic blood pressure (mmHg)	66 ± 3 (52-75)	63 ± 2 (46-74)	65 ± 4 (60-72)	87 ± 3 <sup>a, b, c</sup> (76-96)
<b>Outcomes:</b>				
Gestational age at delivery (weeks)	(-)	39 [38-40]	37 [37-37.5]	35 <sup>b</sup> [34-37]
Neonatal weight (g)	(-)	2986 [2852-3078]	2866 [2643-2998]	1986 <sup>b, c</sup> [1805-2437]
SGA (n)	(-)	0/26	0/3	2/7

PE: preeclampsia, SGA: small for gestational age. Values are the mean ± SEM and (range) or median value with [interquartile range]. a:  $p < 0.05$  vs. non-pregnant women, b:  $p < 0.05$  vs. normal pregnant women, c:  $p < 0.05$  vs. late PE development
