[1] Auroral kilometric radiation (AKR) is known to be transient emissions generated by rapidly accelerated electrons together with sudden auroral activation in the polar magnetosphere. In contrast, the characteristics and relationship with the auroral acceleration of rather continuous AKR emissions are not well understood. We examine the emission using long-term data and report that the continuous AKR emission frequency changes with universal time (UT) as the Earth rotates, indicating that the Earth is a spin-modulated variable radio source. The observed UT variation of AKR frequency means that the acceleration altitude changes periodically with planetary rotation. The observations indicate that the diurnal wobble of the tilted geomagnetic field in the solar wind flow alters the magnetosphere-ionosphere (M-I) coupling state in the polar magnetosphere, giving rise to periodic variation of auroral particle acceleration altitude. These observations of planetary radio wave properties provide insight into the physics of planetary particle acceleration.

1. Introduction

[2] Nonthermal radio emissions from the polar magnetospheres of magnetized planets into space are common [Zarka, 1998]. Jupiter's radiation in the decametric wavelength range was first detected by ground-based observation [Burke and Franklin, 1955] and was attributed to the sporadic, powerful acceleration of energetic particles in the planet's polar magnetosphere. Early solar system exploration led to the discovery of hectometric radiation from Jupiter [Brown, 1974; Desch and Carr, 1974] and kilometric radiation from Saturn [Warwick et al., 1981], Uranus [Warwick et al., 1986], and Neptune [Warwick et al., 1989]. Auroral kilometric radiation (AKR) from the terrestrial polar region has been observed by Earth-orbiting satellites [Dunckel et al., 1970;

Gurnett, 1974]. These planetary radio waves, whose emission frequency is very close to the local electron gyrofrequency, are generated by accelerated auroral electrons through the cyclotron maser instability [Wu and Lee, 1977; Pritchett, 1984; Pritchett and Strangeway, 1985]. The emission efficiency is highly dependent on the ratio of electron cyclotron frequency (f_c) to plasma frequency (f_p), and it attains very high efficiency (more than 1% of beam electron energies) in the tenuous plasma (auroral plasma cavity). The auroral plasma cavity is also the place where auroral electrons are energized along auroral field lines [e.g., Ergun et al., 1998; Strangeway et al., 2001]. Therefore, it is natural to consider that source regions of AKR are almost identical to the auroral particle acceleration region [Morioka et al., 2008, 2010], and such source regions are similar among magnetized planets [Zarka, 1998].

[3] The spectra of planetary radio waves provide information on the structure and dynamics of not only radio source regions but also particle acceleration regions (see Zarka [1998] for a comprehensive review of the auroral radio emissions at the outer planets and Desch and Kaiser [1984] for the radiometric Bode's law). Spectral studies have shown that planetary particle acceleration regions are commonly located at altitudes of 1–2 planetary radii along auroral field lines, as illustrated in Figure 1. This suggests that there exists a scaling law in regard to both their generation mechanism and spatial distribution of the planetary auroral acceleration in the magnetosphere-ionosphere (M-I) coupling regions. The spectra of planetary radio waves thus provide insight into the physics of planetary particle acceleration.

[4] To study the basic coupling process between planetary magnetosphere and ionosphere, statistical investigations on daily, seasonal, and solar cycle variations are important. *Kumamoto and Oya* [1998], *Kasaba et al.* [2000], and

Green et al. [2004] have revealed the long-term characteristics of AKR. Recently, *Panchenko et al.* [2009] have studied the daily variation of AKR and showed that AKR intensities are modulated with a period of ~ 24 h in the northern and southern auroral regions, and the observed frequency range is broader when the geomagnetic axis in a given hemisphere is oriented toward the nightside. These observations suggest that the daily variation of AKR frequency range is not global but out of phase between the two hemispheres. *Lamy et al.* [2010] demonstrated that AKR power shows a clear 24 h modulation. They interpreted the modulation as being due to visibility effects related to the precession of the geomagnetic axis, suggesting that the 24 h modulation is not global but apparent from spacecraft.

[5] In this paper, we report the spin-synchronized frequency variation of AKR that would inform the coupling process between planetary magnetosphere and ionosphere. We examined the universal time (UT) variation of the continuous AKR component using long-term data from the Plasma Wave Instrument [Matsumoto et al., 1994] onboard the GEOTAIL satellite and report that the continuous AKR emission frequency changes globally with UT as the Earth rotates, i.e., the Earth is a spin-modulated variable radio source.

Figure 1. Comparison of planetary radio spectra and radio source altitudes. (a) Planetary radio wave spectra from Jupiter (hectometric radiation), Saturn (Saturn kilometric radiation), Uranus (Uranus kilometric radiation), and Earth (auroral kilometric radiation, AKR). Spectral flux is normalized to a distance of 4 AU. Horizontal axis is the source altitude (in units of planetary radius) along auroral field lines; the altitude is calculated from emission frequency assuming that the emissions occur at the electron gyrofrequency along the field lines. (b) Schematic illustration of planetary radio source distribution in the polar magnetosphere estimated from Figure 1a, indicating that distributions of planetary radio source regions conform to a scaling law.

2. Two Types of AKR

[6] AKR has been studied in relation to auroral breakup and auroral particle acceleration [e.g., Gurnett, 1974; Kaiser and Alexander, 1977; Fairfield et al., 1999] and is widely accepted to be generated by rapidly accelerated electrons accompanying sudden auroral activation in the polar magnetosphere [e.g., Anderson et al., 1998; Strangeway et al., 2001; Morioka et al., 2007]. Figure 2 shows the frequency-time spectrogram (f - t diagrams) of AKR observed by GEOTAIL and AL/AU index on 5 December

Figure 2. Example of transient AKR and continuous AKR. (a) The 24 h f - t diagram of AKR on 3 December 1995 observed by GEOTAIL. GEOTAIL was located in the middle magnetosphere ($r=22.1R_E$ to $29.3R_E$) around the magnetic local midnight (MLT=22.3–0.7 h). The white arrows show transient AKR. The yellow dotted rectangle shows continuous AKR. (b) AU and AL indices.

1995. The arrows in the f - t diagram show the transient AKR with sudden frequency expansion to lower frequencies accompanied with substorm onset [e.g., *Anderson et al.*, 1998; *Morioka et al.*, 2010]. The frequency expansion indicates that the AKR source region extended up to 14,000 km of altitude (see the right-side ordinate). *Morioka et al.*, [2010] showed that this AKR breakup appears at auroral breakup and is composed of two source regions: high-altitude (typically 6000–12,000 km) and low-altitude (typically 3000–5000 km) AKR sources. This sudden frequency expansion of AKR is termed transient AKR in this paper.

[7] In contrast, recent studies have noticed a rather continuous component of AKR [*Panchenko et al.*, 2009; *Morioka et al.*, 2012] that is not directly related to sudden auroral brightening. In the frequency band encircled by a yellow dotted rectangle (from 150 to 700 kHz) in Figure 2a, one can see quasi-continuous banded AKR whose source altitude ranges from 2000 to 8000 km in this case (see the right-side ordinate). This type of AKR, which is termed continuous AKR in this paper, is not directly related to the

substorm onset. This can be recognized from Figure 2: AKR in the frequency band of 150–700 kHz appears continuously even when AL index indicates lower activity (>-100 nT). *Morioka et al.* [2012] showed that this type of AKR is generated in the lower altitude (low-altitude AKR) and correlates well with the energy flux of electrons energized in the inverted-V acceleration region. Thus, the low-altitude AKR is regarded to be the radiation from the self-consistently formed quasi-static inverted-V acceleration region [*Morioka et al.*, 2012]. The formation of the inverted-V acceleration region is strongly related to the mixing of magnetospheric plasma with ionospheric plasma in the M-I coupling region at altitudes of 3000–8000 km [*Chiu and Schulz*, 1978], although the microphysical process to generate the potential drop has yet to be established.

3. Observation

[8] The GEOTAIL spacecraft, launched in 1992, observes radio and plasma waves around the Earth's equatorial plane [*Matsumoto et al.*, 1994] and travels in an orbit suitable for

Figure 3. Universal time variation of AKR frequency and observation geometry. (a) Schematic illustration of AKR observation by GEOTAIL. AKR radiated from the polar magnetosphere with cone shape directivity is detected by GEOTAIL in the nightside magnetosphere. Plasmas in the inner and tail plasma sheet are connected to the M-I coupling region in the polar magnetosphere. (b) f - t diagrams of AKR from 80 to 800 kHz for five successive days (26–30 January 1993). $\sin(\omega t + \theta)$ curves are overlaid on each f - t diagram as a fitted trend of daily frequency variation of the continuous AKR. Black portions on 28 and 29 January indicate the lack of observations due to the satellite operation. (c) The geometrical relationship between the spin axis and the geomagnetic axis at 05:00 UT and 17:00 UT. (d) Superposed daily f - t diagram for January 1993. Right vertical axis shows the estimated source altitude of AKR.

remote observation of AKR phenomena: the emission cones of northern and southern AKR sources cover the orbital plane of the GEOTAIL spacecraft, as shown in Figure 3a. Although the onboard radio receiver was designed to conduct a detailed observation of the wave-particle interaction processes with high frequency-time resolution, we examined the long-term variation of the AKR activity by sharply reducing the resolution. Figure 3b shows daily f - t diagrams for five successive days. During the period, GEOTAIL was in the midnight magnetosphere (magnetic local time (MLT), 00:00–00:20; magnetic latitude (MLAT), 1.6° – 25.1°) with a radial distance of 61 to $93R_E$ (R_E ; Earth radii). The obtained daily f - t diagrams show two types of AKR emissions: transient emissions with frequency expansion to less than 100 kHz (transient AKR) and fairly continuous emissions in a broad frequency band (continuous AKR).

[9] Note that continuous AKR exhibits periodic frequency variation with sinusoidal form synchronized to the Earth's rotation (Figure 3b). The bandwidth of continuous AKR indicates that the AKR source region is widely distributed along auroral field lines. The center frequency variation is approximately represented by $\sin \omega t$ with a phase angle of θ , where ω is the angular frequency of the altitude modulation and t is time, as overlaid on each f - t diagram of Figure 3b. During the northern winter season, the maximum and minimum center frequencies (500 and 200 kHz) appear around 05 and 17 UT, respectively. These specific UTs of 05 and 17 in the case of Figure 3b correspond to the times when the geomagnetic dipole axis, which is tilted and rotates about the Earth's rotational axis, is in the noon-midnight meridian (see Figure 3c). To confirm the regular daily variation, daily f - t diagrams are superposed in f - t plain for a month (January 1993) with the epoch time of 00:00 UT (superposed epoch analysis for time and frequencies) after normalizing AKR intensity at a distance of $30R_E$. The result shown in Figure 3d reveals that the diurnal frequency variation of the form $\sin \omega t$ is statistically significant. The rather flat spectral shape of this superposed f - t diagram is due to the daily continuous AKR band having fairly flat spectra and their superposition.

[10] We also note that, from the monthly superposed f - t diagrams shown in Figure 4, the frequency variation of the form $\sin \omega t$ in Figure 3b is particular to winter and changes to the form $-\sin \omega t$ in the summer season. This phase shift of π rad (180°) in the frequency variation pattern occurs during a rather short period around the vernal and autumnal equinoxes, suggesting that the polarity of geomagnetic field inclination with respect to the Sun-Earth direction (solar wind flow direction) is essential to determine the form of frequency variation.

[11] An important point of the present observation is that the sinusoidal frequency variation with banded structure is global with an in-phase relationship between the Northern and Southern Hemispheres. This indicates that the variation is not governed in only the ionosphere and/or by visibility effects from spacecraft. Figure 5a shows AKR spectrograms for 14–20 April 2001 when the GEOTAIL satellite was in the low-latitude magnetosphere ($-20^{\circ} < \text{MLAT} < 20^{\circ}$) at radial distances of $16.0R_E$ to $30.6R_E$. All spectrograms show the frequency variation of continuous AKR fitted with $-\sin(\omega t + \theta)$, which is consistent with the summer pattern. Figure 5b illustrates MLAT of GEOTAIL during the

Figure 4. Seasonal variation of AKR spectra. Each panel shows monthly superposed epoch analysis of f - t diagrams in a frequency range of 100–800 kHz, during the period when GEOTAIL was in the nightside magnetosphere ($X_{\text{GSM}} < -30R_E$, MLT of 21–03 h) in 1993. Frequency variation of <AKR is fitted by $\sin(\omega t + \theta)$ (blue curve) for winter and $-\sin(\omega t + \theta)$ (yellow curve) for summer.

observations. The evidence that the frequency variation pattern of AKR retains the form $-\sin \omega t$ in both northern and southern latitudes indicates in-phase variation of AKR frequency between hemispheres. Here we conclude that observed AKR frequency variation is global. Figure 6a shows three successive days of AKR spectrograms when GEOTAIL moved from the midnight region to the dayside region (see Figure 6b). The daily frequency variation of AKR with $-\sin \omega t$ form was the same for both the

Figure 5. Global AKR variation. (a) f - t diagrams of AKR from 14 to 20 April 2001. (b) Magnetic latitude of GEOTAIL during the period of AKR observation. The frequency variation pattern is global with an in-phase relationship between the Northern and Southern Hemispheres.

dayside and the nightside hemispheres. This indicates that the observed AKR frequency variation does not depend on the local time of the satellite, that is, it is not apparent frequency variation due to visibility effects of observer points [Lamy *et al.*, 2010], but global frequency variation. Figure 7 shows continuous AKR spectra observed on a day in the northern winter (left panel) and on a day in the northern summer (right panel). In winter, the Imager for Magnetopause-to-Aurora Global Exploration (IMAGE) satellite [Reinisch *et al.*, 2000], which has an eccentric polar orbit over the Northern Hemisphere, observed AKR of the form $\sin \omega t$ (Figure 7a). The GEOTAIL satellite in the equatorial magnetosphere also observed AKR (Figure 7b),

which showed similar frequency variation as did the northern AKR observed by IMAGE. In summer (Figures 7c and 7d), both satellites simultaneously observed AKR of the form $-\sin \omega t$. An equatorial spacecraft observing a frequency variation similar to that of the northern AKR regardless of season indicates that the southern AKR variation should be consistent with the northern AKR variation. Therefore, the AKR frequency variation is global.

[12] The frequency variation of continuous AKR is best detected during periods of relatively low solar activity because AKR observation is sometimes contaminated by solar radio waves; furthermore, the detection of continuous AKR is hampered by frequent and intense transient AKR, which is enhanced significantly during periods of high solar activity. During the time plotted in Figures 3 and 4 (in 1993), the solar activity was in a declining phase after the solar maximum around 1990.

4. Summary and Discussion

[13] We examined the long-term data on AKR and found that the frequency of continuous AKR changes globally with universal time as the Earth rotates, indicating that the Earth is a spin-modulated variable radio source. We also found that the periodic modulation pattern reverses at equinoxes.

[14] From the relationship between continuous AKR and quasi-stable inverted-V acceleration, continuous AKR would relate to a rather stable auroral arc around the auroral oval. The periodic frequency change of continuous AKR during the day means that the altitude of the inverted-V acceleration changes up and down with a period of 24 h along auroral field lines. The observed center frequency variation from 500 to 200 kHz corresponds to the central altitude of the inverted-V acceleration region changing from 3000 to 7000 km. We examine three hypotheses on the origin of the daily up-and-down motion of the acceleration region in the M-I coupling region.

4.1. Ionospheric Origin

[15] The first hypothesis is an ionospheric origin [Panchenko *et al.*, 2009]. Under this hypothesis, solar illumination of the geomagnetic polar region changes diurnally due to the tilt of the geomagnetic dipole with respect to the Earth's rotational axis. This would cause the sinusoidal modulation of the polar ionospheric plasma density, which, in turn, would influence the vertical distribution of the inverted-V acceleration region in the M-I coupling region. However, this hypothesis does not agree with the observations: the model predicts antiphase spectral variation between hemispheres, which is not consistent with the observations.

4.2. Magnetospheric Origin 1 (Plasma Anisotropy)

[16] The second hypothesis is a magnetospheric origin. The magnetospheric configuration is controlled by the solar wind. The configuration varies diurnally because the orientation of the Earth's magnetic dipole with respect to the solar wind flow changes as the Earth rotates. This aspect is demonstrated by the empirical magnetospheric magnetic field model [e.g., Tsyganenko, 1989], as shown in Figure 8a for 1 day in winter and in Figure 8d for 1 day in summer, where the field line of 66° invariant latitude at the midnight meridian is traced as a representative inverted-V field line.

MORIOKA ET AL.: UNIVERSAL TIME CONTROL OF AKR

Figure 6. Universal frequency variation of continuous AKR. (a) f - t diagram from 21 to 23 April 2006 with frequency variation with form $-\sin \omega t$. (b) Trajectory of GEOTAIL during the period in X - Y plane of GSE coordinates. While the spacecraft moved from the nightside magnetosphere to the dayside magnetosheath, AKR spectral variation retained a constant form, indicating that AKR frequency variation is not apparent but global.

Figure 7. Two satellite observations of AKR from equatorial (GEOTAIL) and northern high latitudes (IMAGE). (a) AKR spectrogram observed from the northern high latitude on 11 November 2000. (b) Same as Figure 7a but from the equatorial region. Continuous AKR showed in-phase frequency variation with the form $\sin \omega t$ between the northern high latitude and the equator. (c) AKR spectrogram observed from the northern high latitude on 11 June 2002. (d) Same as Figure 7c but from the equatorial region. Continuous AKR observed in northern summer showed in-phase frequency variation with the form $-\sin \omega t$ between the northern high latitude and the equator. Note that spectral axes of IMAGE observation in Figures 7a and 7c are displayed in logarithmic scale.

MORIOKA ET AL.: UNIVERSAL TIME CONTROL OF AKR

Figure 8. Relationship between frequency variation of continuous AKR and magnetospheric configuration. (a) Configuration of the magnetospheric magnetic field line of 66° invariant latitude at the midnight meridian on 26 January 1993. Field lines are traced by using the Tsyanenko 89 magnetic field model. (b) Apex height (in units of the Earth radius) of the field line of 66° invariant latitude with respect to universal time (UT) on 26 January 1993. (c) f - t diagram of AKR on the same day. (d) Same as Figure 8a but on 24 July 1993, almost half a year later. (e) Same as Figure 8b but on 24 July 1993. (f) Same as Figure 8c but on 24 July 1993.

The nightside geomagnetic tail moves up and down during the day, and the movement pattern differs between summer and winter, owing to the seasonal variation of the Earth's axial inclination with respect to the Sun. This dynamical variation of the magnetospheric configuration results in a periodic change in the length of the magnetic field line in each meridian plane in the magnetosphere (Figures 8a and 8d). Over the course of a day, the apex of the field lines connected to the inverted-V acceleration region sweeps the plasma sheet between the near-tail region ($10R_E$) and the far-tail region ($20R_E$) with a quasi-sinusoidal form and an inverse phase relationship between winter and summer (Figures 8b and 8e).

[17] Note here that the daily sweep range of the inverted-V field lines corresponds to the transition region from the dipole-like (inner plasma sheet) to the tail-like field lines (tail plasma sheet). Figure 9 shows radial dependence of plasma parameters in the plasma sheet transition region from $8R_E$ to $20R_E$ obtained from plasma observation by the Time History of Events and Macroscale Interactions during Substorms (THEMIS) mission [Angelopoulos, 2008; McFadden *et al.*, 2008] for the period from December 2008 to April 2009. The data shown are restricted to energy of 10–30 keV in the plasma sheet ($\beta > 1$), magnetic local times of 21:00 to 03:00, and auroral electrojet activity index of 100–300 nT. The radial profiles obtained do not suffer materially from the lack of inclusion of a higher-energy component (>30 keV) [Wang *et al.*, 2011]. The observation showed that the plasma characteristics change with radial

distance: as distance from the Earth increases, plasma temperature increases and plasma density and temperature anisotropy ($A = T_{\text{perpendicular}}/T_{\text{parallel}}$) decrease.

[18] These changes in the parameters of the plasma sheet along the inverted-V field lines would play an important role in the M-I coupling region: the equilibrium state and its variation in the ionospheric and magnetospheric plasma determine the potential structure and its dynamics in the M-I coupling region [Chiu and Schulz, 1978]. Thus, the inverted-V acceleration region forms, and its vertical (field aligned) motion depends on the mixing state of the two plasmas, although, presently, it is not immediately evident why plasmas in the hotter plasma sheet region (i.e., the tail plasma sheet) raise the altitude of the acceleration region, and vice versa.

[19] The pattern of the vertical motion would have an opposite phase between summer and winter because the apex height of field lines with respect to UT is reversed around the vernal and autumnal equinoxes. Thus, the auroral field lines sweeping the transitional plasma sheet region during a day can induce the periodic up-and-down motion of the auroral electron acceleration region, which modulates the AKR frequency. The present hypothesis can be tested through numerical simulation by precisely solving the equilibrium of the two-component plasma in the M-I coupling region under a realistic plasma distribution and magnetic field configuration.

[20] The scenario proposed above is based on the correlation between apex height of auroral field line and AKR

Figure 9. Radial dependence of plasma parameters in the plasma sheet from $8R_E$ to $20R_E$. (a) Electron and ion density. (b) Ion temperature for perpendicular and parallel components. (c) Electron temperature for perpendicular and parallel components. (d) Temperature anisotropy for ions and electrons. (e) Configuration of magnetic field and plasma sheet. Magnetic fields connected to the M-I coupling region periodically sweep a certain range (blue arrow) of plasma sheet as the Earth rotates.

frequency. The correlation does not necessarily mean causality at this time, although the scenario is one of the probable working hypotheses.

4.3. Magnetospheric Origin 2 (Force Balance)

[21] The following alternative explanation of magnetospheric origin is also considered based on the force balance in the inner plasma sheet and the resultant field-aligned current modulation. (i) The inner edge of the plasma sheet, the region between the dipole and tail-like field lines, is where the auroral acceleration occurs [Jiang *et al.*, 2012; Sergeev *et al.*, 2012]. (ii) The location of the inner edge of the plasma sheet is governed by the force balance between the backward pull, due to solar wind force, of the tail current sheet on the magnetopause and the pull of the Earth's dipole on the current itself. The equilibrium distance is set by this balance. Under a given set of solar wind conditions, the nominal location of the inner edge of the plasma sheet is

about $10R_E$. (iii) When there is a dipole tilt, the tailward force component acting on the tail remains the same, but the Earthward force component along the dipole equator is at an angle (the tilt angle); to exert the same force Earthward, the current sheet therefore must move Earthward into a stronger field. This happens by changing the mapping of auroral field lines to a smaller equatorial distance at high tilt. (iv) The mapping region thus moves to a lower altitude at a higher tilt, which corresponds to larger equatorial field magnitude. This means that the magnetic gradients are steeper, including plasma pressure gradients. Therefore, the region of auroral generation in the equatorial magnetosphere has higher current generation capacity. (v) This higher current demand causes the auroral generation region to intensify and causes the decrease in potential to expand further to lower altitude.

[22] In conclusion, the present observation showed that terrestrial AKR changes its emission frequency with universal time (the Earth is a spin-modulated variable radio source) and suggested that the diurnal wobble of the tilted geomagnetic field in the solar wind flow alters the magnetosphere-ionosphere (M-I) coupling state in the polar magnetosphere. Magnetized planets such as Jupiter, Saturn, Uranus, and Neptune emanate auroral radio emissions [Zarka, 1998]. Those planets with significant dipole tilt would be expected to have the same type of UT variation affecting those emissions as occurs at Earth. Similarly, in the event that AKR-type emissions are detected from extrasolar planets, the emissions from those planets should exhibit this modulation if they have dipole tilts similar to those at Earth.
