Influence of surface displacement on solid state flow induced by horizontally heterogeneous Joule heating in the inner core of the Earth

Shin-ichi Takehiro

Research Institute for Mathematical Sciences, Kyoto University, Sakyo-ku, Kyoto 606-8502, Japan

Abstract

We investigate the influence of surface displacement on fluid motions induced by horizontally heterogeneous Joule heating in the inner core. The difference between the governing equations and those of Takehiro (2011) is the boundary conditions at the inner core boundary (ICB). The temperature disturbance at the ICB coincides with the melting temperature, which varies depending on the surface displacement. The normal component of stress equalizes with the buoyancy induced by the surface displacement. The toroidal magnetic field and surface displacement with the horizontal structure of Y_2^0 spherical harmonics is given. The flow fields are calculated numerically for various amplitudes of surface displacement with the expected values of the parameters of the core. Further, by considering the heat balance at the ICB, the surface displacement amplitude is related to the turbulent velocity amplitude in the outer core, near the ICB. The results show that when the turbulent velocity is on the order of 10^{-1} – 10^{-2} m/s, the flow and stress fields are similar to those of Takehiro (2011), where the surface displacement vanishes. As the amplitude of the turbulent velocity decreases, the amplitude of the surface displacement increases, and counter flows from the polar to equatorial regions emerge around the ICB, while flow in the inner regions is directed from the equatorial to polar regions, and the non-zero radial component of velocity at the ICB remains. When the turbulent velocity is on the order of 10^{-4} – 10^{-5} m/s, the radial component of velocity at the ICB vanishes, the surface counter flows become

stronger than the flow in the inner region, and the amplitude of the stress field near the ICB dominates the inner region, which might be unsuitable for explaining the elastic anisotropy in the inner core.

Keywords: Inner core flows, Elastic anisotropy, Turbulent velocity in the outer core, Interaction between inner and outer core

1. Introduction

The origin of the elastic anisotropy of the Earth's inner core (e.g. Poupinet et al., 1983; Morelli et al., 1986; Souriau, 2007) is considered to be the alignment of texture formed along the solidification of the core (e.g. Karato, 1993; Bergman, 1997) or the alignment of the preferred orientation of crystals by plastic deformation of fluid motions (e.g. Jeanloz and Wenk, 1988; Yoshida et al., 1996; Karato, 1999; Buffett and Wenk, 2001). The depth dependency of the anisotropy is difficult to explain by the solidification mechanism, whereas the various factors driving solid state flow in the inner core considered thus far do not appear to yield sufficiently strong stresses to generate elastic anisotropy. Takehiro (2011) proposed Joule heating of the magnetic field penetrating diffusively from the inner core boundary (ICB) as a possible source of inner core flows. His specific calculation in the case of a toroidal magnetic field with the horizontal structure of Y_2^0 spherical harmonics showed that internal flows of sufficient magnitude can be induced to explain the elastic anisotropy. The obtained solution consists of downward flow in the equatorial region and upward flows in the polar region, and has a non-zero radial velocity component at the ICB, causing mass exchange between the inner and outer core. This feature is a result of the constant normal stress boundary condition at the ICB, and it is implicitly assumed that the phase change occurs instantaneously at the ICB. However, the actual speed of the phase change is finite. If the speed of the phase change is slow enough, the ICB would be deformed, and surface displacement is induced by the non-zero radial velocity at the ICB. This surface displacement may prevent inner core flows due to the buoyancy force originating from the density contrast between the inner and outer core.

In this paper, we investigate the influence of surface displacement on fluid motions

induced by horizontally heterogeneous Joule heating in the inner core. We examine the extent of development of surface displacement, and modification of the flow field of the inner core. Sec. 2 is a description of our model. In Sec. 3, numerical results are presented for various amplitudes of surface displacement at the ICB. Further, the equilibrated amplitude of surface displacement is related to the magnitude of turbulent velocity in the outer core just above the ICB. Sec. 4 summarizes the results, and discusses whether Joule heating could be the origin of the elastic anisotropy of the Earth's inner core.

2. Model

We consider an MHD Boussinesq fluid in a sphere. The governing equations determining steady flow and temperature disturbance induced by differential Joule heating are as follows (Takehiro, 2011):

$$0 = -\frac{1}{\rho_0} \nabla p + \alpha T \mathbf{g} + \nu \nabla^2 \mathbf{v}, \quad (1)$$

$$v_r \frac{dT_B}{dr} = \kappa \nabla^2 T + \frac{Q_J}{\rho_0 C_p}, \quad (2)$$

$$\nabla \cdot \mathbf{v} = 0. \quad (3)$$

$\mathbf{v}$ is velocity, v_r is the radial component of velocity, ρ_0 is the mean density of the Boussinesq fluid, p is pressure, T is the temperature disturbance, and dT_B/dr is the radial temperature gradient of the basic state. Gravity induced by the mass of the sphere itself is a spherically symmetric distribution, $\mathbf{g} = -(g_0/a)\mathbf{r}$, where g_0 is the gravitational acceleration at the surface, a is the radius of the sphere, and $\mathbf{r}$ is the position vector in the radial direction. $Q_J = |\mathbf{J}|^2/\sigma = |\nabla \times \mathbf{B}|^2/\mu\sigma$ is the Joule heating produced by the magnetic field $\mathbf{B}$ diffusing from the outer boundary (ICB) to the interior, where μ and σ are the magnetic permeability and electric conductivity. Note that eqs. (1) and (2) neglect second order nonlinear terms, the validation of which was discussed in Takehiro (2011).

The difference between these governing equations and those of Takehiro (2011) is the boundary conditions at the ICB, where the effects of surface displacement emerge. The normal stress is balanced at the surface with a buoyancy force proportional to the

density difference of the inner and outer core. The temperature at the surface is equal to the melting point, which is varied by the surface displacement. The tangential stresses vanish at the surface.

$$\sigma_{rr} = -p + 2\rho_0 v \frac{\partial v_r}{\partial r} = -\Delta\rho gh, \quad (4)$$

$$\sigma_{r\theta} = \rho_0 v \left(\frac{1}{r} \frac{\partial v_r}{\partial \theta} + \frac{\partial v_\theta}{\partial r} - \frac{v_\theta}{r} \right) = 0, \quad \sigma_{r\phi} = \rho_0 v \left(\frac{\partial v_\phi}{\partial r} - \frac{v_\phi}{r} + \frac{1}{r \sin \theta} \frac{\partial v_r}{\partial \phi} \right) = 0, \quad (5)$$

$$T = \frac{dT_m}{dr} h, \quad \text{at } r = a. \quad (6)$$

Here, $\Delta\rho$ is the density difference between the inner and outer core, $h(\theta, \phi)$ is the surface displacement distribution, θ and ϕ are colatitude and azimuth, respectively, and dT_m/dr is the melting temperature gradient. For simplicity, stress and temperature are evaluated at $r = a$, which is the boundary where the surface displacement vanishes.

The non-divergent flow field is expressed with the toroidal and poloidal potentials, ψ and Φ , defined by

$$\mathbf{v} = \nabla \times (\psi(r, \theta, \phi) \mathbf{r}) + \nabla \times \nabla \times (\Phi(r, \theta, \phi) \mathbf{r}), \quad (7)$$

Eqs. (1) and (2) become

$$\nabla^2 L_2 \psi = 0, \quad (8)$$

$$v \nabla^2 L_2 \nabla^2 \Phi - \alpha(g_0/a) L_2 T = 0, \quad (9)$$

$$\frac{L_2 \Phi}{r} \frac{dT_B}{dr} = \kappa \nabla^2 T + \frac{Q_J}{\rho_0 C_p}. \quad (10)$$

From Eq. (8), $\psi \equiv 0$, meaning that the toroidal component is not induced. Removing the temperature disturbance from Eqs. (9) and (10),

$$\frac{L_2 \Phi}{r} \frac{dT_B}{dr} - \frac{\kappa v}{\alpha(g_0/a)} \nabla^2 \nabla^2 \Phi = \frac{Q_J}{\rho_0 C_p}. \quad (11)$$

The boundary conditions are expressed with the velocity potentials. By taking the horizontal divergence of Eq. (1), pressure can be expressed with the potentials. Then,

Eqs. (4), (5), and (6) become

$$\rho_0 v \frac{\partial}{\partial r} r \left(-\nabla^2 \Phi + \frac{2L_2 \Phi}{r^2} \right) = -\Delta\rho gh \text{ at } r = a, \quad (12)$$

$$\frac{\partial^2 \Phi}{\partial r^2} - \frac{2\Phi}{r^2} + \frac{L_2 \Phi}{r^2} = 0 \text{ at } r = a, \quad (13)$$

$$\frac{va}{\alpha g_0} \nabla^2 \nabla^2 \Phi = \frac{dT_m}{dr} h, \text{ at } r = a. \quad (14)$$

Following the procedure of Takehiro (2011), the governing equations are non-dimensionalised, considering the dominance of advection of basic temperature. Using the temperature rising rate $|Q_J|/\rho C_p$ and the difference between basic and adiabatic temperature at the center, ΔT , the time scale is chosen to be $\Delta T \rho C_p / |Q_J|$. The length scale is chosen to be the radius of the sphere a . Then, the poloidal potential should be normalised by $(|Q_J|/\rho C_p)(a^2/\Delta T)$. Eq. (11) becomes

$$\frac{L_2 \Phi}{r} \frac{dT_B}{dr} - \frac{1}{R} \nabla_2^2 \nabla_2^2 \Phi_* = q_J, \quad (15)$$

where $q_J = Q_J/|Q_J|$ is non-dimensionalised Joule heating, and R expresses the strength of stable stratification,

$$R = \frac{\alpha g_0 \Delta T a^3}{\kappa \nu}. \quad (16)$$

The boundary conditions, Eqs. (12), (13), and (14) are normalised as:

$$\frac{\partial}{\partial r} r \left(-\nabla^2 \Phi + \frac{2L_2 \Phi}{r^2} \right) = -R_s h, \text{ at } r = 1, \quad (17)$$

$$\frac{\partial^2 \Phi}{\partial r^2} - \frac{2\Phi}{r^2} + \frac{L_2 \Phi}{r^2} = 0 \text{ at } r = 1, \quad (18)$$

$$\frac{1}{R} \nabla^2 \nabla^2 \Phi = -\Gamma_m h, \text{ at } r = 1, \quad (19)$$

where

$$\Gamma_m = \frac{(-dT_m/dr)a}{\Delta T} = \frac{(dT_m/dP)\rho g a}{\Delta T}, \quad R_s = \frac{\rho C_p \Delta T}{|Q_J|} \frac{\Delta \rho g a}{\rho_0 \nu}. \quad (20)$$

Given the values of R , Γ_m , and R_s , the steady flow and temperature disturbance fields can be obtained from these equations by setting the distributions of basic temperature gradient dT_B/dr , Joule heating q_J , and surface displacement h .

To solve the governing equations with the boundary conditions numerically, the poloidal potential Φ is expanded with spherical harmonic functions in the horizontal directions, and with the polynomials developed by Matsushima and Marcus (1995) in the radial direction. The surface displacement h is also expanded with spherical harmonics. Then, the problem becomes a system of linear equations for each spherical harmonic component of Φ , since the governing equations and boundary conditions are linear. The polynomials for the radial direction are calculated to the 63rd degree.

In the same manner as the specific calculation of Takehiro (2011), the toroidal magnetic field component with spherical harmonics of degree 2 and order 0 is imposed

Figure 1: Flow fields in the inner core induced by Joule heating of Y_2^0 type for various amplitudes of surface displacement. From left to right, given amplitudes of surface displacement that are 0, 0.006, 0.06, 0.6, 1.2, and 1.8m in the case of $B = 10^{-1}$ T (or 0, 0.00006, 0.0006, 0.006, 0.012, and 0.018m in the case of $B = 10^{-2}$ T). These panels correspond to cases with turbulent velocities in the outer core of $u' \sim \infty, 1.4 \times 10^{-1}, 1.4 \times 10^{-2}, 10^{-3}, 2.6 \times 10^{-4}$, and 2.1×10^{-5} m/s, respectively.

on the ICB. The Joule heating distribution in the inner core produced by the steady magnetic field diffusing from the ICB becomes $q_J = r^2 Y_2^0(\cos \theta)$, removing the homogeneous component, and its amplitude is given by $|Q_J| = 8B^2/(\sigma\mu^2 a^2)$ (Takehiro, 2011). Since the governing equations of the system are linear, the surface displacement distribution at the ICB induced by the flow driven by Joule heating is also proportional to Y_2^0 . Following the setup of Takehiro (2011), the non-dimensionalised temperature gradient of the basic state dT_B/dr is assumed to be in proportion to r . Table 1 summarizes the values of the parameters used for the numerical calculations. Note that larger values of electric conductivity and thermal diffusivity recently estimated by first principle calculations (e.g. Pozzo et al., 2012) are adopted than those used in Takehiro (2011). Using these values, the non-dimensional parameters are estimated as:

$$\begin{aligned} R &= \frac{\alpha g \Delta T a^3}{\kappa \nu} \sim 1.6 \times 10^7, & R_s &= \frac{\rho C_p \Delta T}{Q_J} \frac{\Delta \rho g a}{\rho_0 \nu} \sim 3.1 \times 10^8 - 3.1 \times 10^{10}, \\ \Gamma_m &= \frac{m_m \rho g a}{\Delta T} \sim 20.4. \end{aligned} \quad (21)$$

3. Results

Fig. 1 shows the obtained flow field for several amplitudes of surface displacement. When the magnitude of magnetic field at the ICB is $B = 10^{-1}$ T, the distribution

Magnetic field at ICB B	$10^{-1}-10^{-2}$ T
Electric conductivity σ	1.2×10^6 Sm
Magnetic permeability μ	$4\pi \times 10^{-7}$
Inner core radius a	1.2×10^6 m
Inner core density ρ_0	1.2×10^4 kg/m ³
Density difference between inner and outer core $\Delta\rho$	5×10^2 kg/m ³
Specific heat C_p	850 J/kg·K
Gravity at ICB g	5 m/s ²
Difference between basic and adiabatic temperature at the center ΔT	30 K
Thermal expansion coefficient α	1×10^{-5} 1/K
Thermal diffusivity κ	2×10^{-5} m ² /s
Viscosity	10^{17} Pa·s
Latent heat L	10^6 J/kg
Adiabatic temperature gradient near ICB m_{ad}	6×10^{-9} K/Pa
Melting temperature gradient near ICB m_m	8.5×10^{-9} K/Pa
Turbulent velocity near ICB in the outer core u'	$10^{-1}-10^{-5}$ m/s

Table 1: Values of inner core model parameters used for numerical calculations. Physical properties of the inner core are from Stacey and Davis (2008), σ and κ are from Pozzo et al. (2012), m_{ad} and m_m are from Alboussiere et al. (2010), and u' is from Loper (2007).

101 of the flow field in the case with a surface displacement magnitude of 0.006–0.06m is
102 similar to the case of no surface displacement. The fact that the surface displacement
103 does not affect significantly to the fluid field means that timescale of phase change at
104 ICB is small compared with that of surface deformation in these cases. Recalling the
105 result of Takehiro (2011), the solid state flow is mainly driven so that temperature in-
106 crease/decrease by heterogenous Joule heating balances with the advection of the basic
107 temprature. As a result, the flow velocity is essentially independent of the viscosity
108 of the inner core. In other words, since the timescale of advection of temperature dis-
109 turbance is small compared to that of advection of basic temperature, the inner core
110 continuously deforms to keep the isotherms as close as possible to spherical surfaces.
111 The amplitude of induced solid state flow is $O(10^{-10})$ m/s, which is smaller than the
112 estimation by Takehiro (2011) due to the larger value of electric conductivity. As the
113 amplitude of surface displacement increases to $O(1\text{m})$, the counter flow from the poles
114 to the equator emerges, and is strengthened below the ICB. However, in the deep re-
115 gion, the flows directed from the equator to the poles still exist, and the magnitude of
116 the internal flows is similar to the case with no surface displacement. The normal com-
117 ponent of velocity at the ICB vanishes when the amplitude of surface displacement is
118 about 1.8 m, where the amplitude of surface velocity becomes 3×10^{-10} m/s. As the
119 ICB approaches to a closed boundary, the amplitude of flow below the ICB increases,
120 because mass flux from the equatorial to the polar regions by the deep flows (which
121 does not change its amplitude) must return through the thin layer below the ICB. Fig. 2
122 shows the direction and magnitude of the principal stresses of the flow fields presented
123 in Fig. 1. When the magnitude of the magnetic field at the ICB is $B = 10^{-1}$ T, the
124 distribution of the stress field in the case where the amplitude of surface displacement
125 of 0.006m is similar to the case of no surface displacement, Its magnitude is $O(10)$ Pa,
126 which is smaller than the estimation by Takehiro (2011) due to the larger value of elec-
127 tric conductivity. The principal stress below the ICB is weak and directed in a different
128 direction from that in the deep region. As the amplitude of surface displacement in-
129 creases to $O(1\text{m})$, the magnitude of principal stress below the ICB becomes as large
130 as $O(10^2)$ Pa and its direction is parallel to the equatorial plane. However, in the deep
131 region, the principal stress keeps its magnitude and is directed poleward, which is the

Figure 2: Direction and magnitude of principal stresses of the flow fields presented in Fig. 1. From left to right, given amplitudes of surface displacements that are 0, 0.006, 0.06, 0.6, 1.2, and 1.8m in the case of $B = 10^{-1}$ T (or 0, 0.00006, 0.0006, 0.006, 0.012, and 0.018m in the case of $B = 10^{-2}$ T). These panels correspond to cases with turbulent velocities in the outer core of $u' \sim \infty, 1.4 \times 10^{-1}, 1.4 \times 10^{-2}, 10^{-3}, 2.6 \times 10^{-4}$, and 2.1×10^{-5} m/s, respectively. The scale of the arrows in the three right panels are 1/5 of the arrows in the three left panels.

132 same as the case with no surface displacement.

133 The numerical calculations presented so far are performed by giving the amplitude
134 of surface displacement as an external parameter. In order to determine equilibrium
135 amplitude of surface displacement, let us consider thermal balance at the phase bound-
136 ary. Heat transported to the ICB by turbulent velocity u' in the outer core is assumed
137 to be estimated by the difference between the adiabatic and melting temperature as
138 (Alboussiere et al., 2010):

$$u' C_p \delta T \sim u' C_p (m_m - m_{ad}) \rho g h,$$

139 where δT is the adiabatic and melting temperature difference, and m_m and m_{ad} are
140 the melting and adiabatic temperature gradients near the ICB, respectively. This heat
141 transport should be balanced by the latent heat for melting of the solid material ejected
142 from the ICB, $v_r(r = a)L$, where $v_r(r = a)$ is radial flow at the ICB, and L is the latent
143 heat for melting. Then, we have

$$u' = \frac{v_r(r = a)L}{C_p(m_m - m_{ad})\rho g h}. \quad (22)$$

144 u' are evaluated by using the numerical results of $v_r(r = a)$ and h . Table 2 shows
145 the values of turbulent velocity in the outer core u' for various values of the amplitudes
146 of surface displacement and radial flow at the ICB. When the turbulent velocity is

h (m)	0	0.006	0.06	0.6	1.2	1.8
$v_r(r=a)$ (m/s)	1.1×10^{-10}	1.1×10^{-10}	1.1×10^{-10}	7.6×10^{-11}	4.0×10^{-11}	4.9×10^{-12}
u' (m/s)	∞	1.4×10^{-1}	1.4×10^{-2}	10^{-3}	2.6×10^{-4}	2.1×10^{-5}

Table 2: Turbulent velocity in the outer core u' calculated with equilibrium amplitudes of surface displacement and radial flow at the ICB in the case of $B = 10^{-1}$ T.

147 sufficiently large ($u' \sim 10^{-1}$ – 10^{-2} m/s), the amplitude of surface displacement becomes
148 small ($h \sim 10^{-2}$ m), since the growth time scale of surface displacement is large enough
149 compared to the time scale of phase change. Then, the velocity and stress fields in the
150 inner core are similar to those in the case of no surface displacement (the left three
151 panels of Figs. 1 and 2). In contrast, when the turbulent velocity is small ($u' \sim 10^{-3}$ –
152 10^{-5} m/s), the surface displacement becomes as large as $h \sim 1$ m, since the growth
153 time scale of surface displacement is small compared to the time scale of phase change.
154 Then, the radial flows at the ICB are weakened, and strong return flows from the poles
155 to the equator emerge near the ICB, while flows from the equator to the poles with
156 amplitudes similar to the $h = 0$ case remain in the interior (the right three panels of
157 Figs. 1 and 2).

158 4. Conclusions and discussions

159 We investigated the fluid motions induced by horizontally heterogeneous Joule
160 heating in the inner core by taking into account the surface displacement. Given an
161 ICB toroidal magnetic field of Y_2^0 type, the distributions of the flow and stress fields
162 were calculated for various values of surface displacement amplitude. Further, the re-
163 lationship between the amplitudes of surface displacement and radial flow at the ICB
164 was deduced from the heat balance at the ICB, and, as a result, the distributions of the
165 flow and stress fields were obtained for various values of turbulent velocity near the
166 ICB in the outer core. The results show that when the turbulent velocity is sufficiently
167 large ($u' \sim 10^{-1}$ – 10^{-2} m/s), the surface displacement does not develop significantly,
168 and the velocity and stress fields in the inner core are similar to those in the case of
169 no surface displacement (the left three panels of Figs. 1 and 2), which may explain
170 the elastic anisotropy, although those magnitudes are estimated as $O(10^{-10})$ m/s and

171 $O(10)\text{Pa}$ ($O(10^{-12})\text{m/s}$ and $O(0.1)\text{Pa}$ for $B = 10^{-2}\text{ T}$), which are smaller than the es-
172 timation by Takehiro (2011) due to the smaller value of electric conductivity adopted
173 here. In contrast, when the turbulent velocity is small ($u' \sim 10^{-3}\text{--}10^{-5}\text{ m/s}$), the rate
174 of phase change decreases at the ICB, and the surface displacement develops signifi-
175 cantly. The radial flows at the ICB is weakened, and strong return flows from the poles
176 to the equator emerge near the ICB (the right three panels of Figs. 1 and 2), which may
177 not be suitable for explaining the origin of anisotropy in the inner core. These results
178 suggest that the amplitude of turbulent velocity in the outer core should be as large as
179 $u' \sim 10^{-2}\text{ m/s}$ in order to attribute the origin of anisotropy in the inner core to the fluid
180 motions induced by heterogeneous Joule heating.

181 The amplitude of turbulent velocity in the outer core is considered to be on the order
182 of 10^{-3} m/s or 10^{-4} m/s (Alboussiere et al., 2010). However, Loper (2007) theoretically
183 estimated the velocity amplitude of compositional plumes near the ICB, and suggested
184 that their value could be $1.3 \times 10^{-3}\text{ m/s} - 0.25\text{ m/s}$. This suggests that the origin of
185 elastic anisotropy in the inner core could be attributed to Joule heating.

186 The advantage of the present model is that the velocity amplitude in the interior of
187 the inner core does not depend on viscosity, the value of which is quite ambiguous in
188 the inner core. However, the present estimation may be affected by other parameters.
189 For example, smaller toroidal magnetic field at ICB B brings smaller Joule heating and
190 then, smaller velocity amplitude. The value 10^{-1} T used in the present study may be
191 rather large, since several recent studies proposed the averaged values of magnetic field
192 of a few mT in the interior of the present outer core (e.g. Christensen and Aubert, 2006;
193 Gillet et al., 2010; Buffett, 2010). The toroidal part of the magnetic field at the ICB
194 may be significantly larger, for example, due to the differential rotation of the inner core
195 (e.g. Aurnou et al., 1998), however, recent seismological studies yield relatively small
196 rotation rates (e.g. Tkalčić et al., 2013) or infer no differential rotation (e.g. Mäkinen
197 and Deuss, 2011). The value of difference between basic and adiabatic temperature
198 at the center also affects the estimation, which is influenced by thermal history of the
199 inner core. When the temperature difference becomes small, the velocity amplitude
200 increases. Thermal history of the inner core should be reexamined with a recently
201 updated value of thermal conductivity to evaluate the temperature difference.

ICB tends to be impermeable at $u' \sim O(10^{-3})$ m/s in our estimation. This transition turbulent velocity in the outer core u'_c depends on several parameters. In order to clear this issue, let us remove h from the boundary conditions (13) and (14) using (22). After non-dimensionalizing these equations, we obtain,

$$\frac{\partial}{\partial r} r \left(-\nabla^2 \Phi + \frac{2L_2 \Phi}{r^2} \right) = -\mathcal{P}_\eta \frac{L_2 \Phi}{r}, \quad \nabla^2 \nabla^2 \Phi = -\mathcal{P}_T \frac{L_2 \Phi}{r}, \quad \text{at } r = 1, \quad (23)$$

where

$$\mathcal{P}_D = \frac{\delta \rho g a}{\rho \nu} \cdot \frac{L}{C_p(m_m - m_{ad})\rho g u'} = \frac{\tau_p}{\tau_\eta}, \quad \mathcal{P}_T = \frac{\alpha g m_m \rho g a^2}{\nu} \cdot \frac{L}{C_p(m_m - m_{ad})\rho g u'} = \frac{\Delta T_m}{\Delta T_v}. \quad (24)$$

$\mathcal{P}_D$ is the non-dimensional parameter expressing the effect of phase change on the dynamical balance at ICB (Deguen et al., 2013), meaning the ratio between the phase change timescale $\tau_p = L/[C_p(m_m - m_{ad})\rho g u']$ and the viscous relaxation timescale $\tau_\eta = (\rho \nu)/(\delta \rho g a)$. $\mathcal{P}_T$ is the non-dimensional parameter expressing the effect of phase change on the thermal balance at ICB, interpreted as the ratio between the temperature scale induced by surface displacement $\Delta T_m = m_m \rho g \tau_p V$ and that induced by viscous and buoyancy forces balance $\Delta T_v = (\nu V)/(\alpha g a^2)$, where V is the velocity scale. Whether ICB becomes permeable or impermeable is determined by the values of $\mathcal{P}_D$ and $\mathcal{P}_T$. When both $\mathcal{P}_D$ and $\mathcal{P}_T$ approaches 0, instantaneous phase change occurs at and ICB becomes fully permeable. In contrast, either $\mathcal{P}_D$ or $\mathcal{P}_T$ is sufficiently large, ICB becomes impermeable due to slow phase change. Both $\mathcal{P}_D$ and $\mathcal{P}_T$ depend on several parameters, respectively. For example, if viscosity becomes large and other parameters are fixed, both $\mathcal{P}_D$ and $\mathcal{P}_T$ is reduced, resulting permeable ICB. In other words, larger viscosity gives smaller transition turbulent velocity u'_c . Note that the conditions $\mathcal{P}_D \sim 1$ and $\mathcal{P}_T \sim 1$ and the values of the parameters used in this study give $u'_c \sim 0.2$ m/s and 0.03 m/s, seeming to contradict the present numerical results. However, since the thickness of the boundary layer is about 0.2 in our solutions, the lefthandsides of Eq. (23) should not be assumed as $O(1)$ but $O(0.2^3)$ and $O(0.2^6)$, yielding $u'_c \sim O(10^{-3})$ m/s and $O(10^{-6})$ m/s, which is consistent with the numerical results.

The present results show that when the surface displacement of the inner core is significant the solid state flow is restricted to the surface of the ICB where anisotropy in the present inner core is weaker. It seems that Joule heating is unsuitable for the

229 origin of the elastic anisotropy. However, the mechanism proposed here might play a
230 important role in the past, possibly because heat flux through the core-mantle boundary
231 was larger, yielding stronger magnetic field in the outer core. There is a possibility that
232 the elastic anisotropy was produced by the solid state flow driven by Joule heating
233 during the growing stage of the inner core, and is now buried while the mechanism is
234 not operating (e.g. Deguen and Cardin, 2009).
