Abstract

Purpose: To investigate the relationship between impairment of cone/rod photoreceptors and changes in optical coherence tomography (OCT) findings.

Methods: We retrospectively reviewed the clinical records of 35 patients with cone-rod dystrophy (CRD) and 35 visual acuity-matched patients with retinitis pigmentosa (RP). The presence or absence of the external limiting membrane (ELM), inner segment ellipsoid (ISe), interdigitation zone (IZ), and foveal cavitation (hyporeflective space in the outer retina) were determined using OCT image evaluation.

Results: There were no statistical differences in the number of CRD and RP patients with an intact ELM and ISe. None of the CRD patients had an intact IZ, but 20% of RP patients did (P = 0.011). In addition, foveal cavitation tended to be observed more frequently in CRD patients than (25.7%) than in RP patients (5.7%) despite the difference was not significant after the correction of multiple comparison.

Conclusions: Eyes with CRD and RP had significant differences in foveal morphology, even when visual acuity was matched. This result supports the notion that absence of an IZ and the presence of foveal cavitation is related to cone-dominant photoreceptor impairment.
Keywords: cone-rod dystrophy; retinitis pigmentosa; optical coherence tomography
Introduction

Major advances in ophthalmologic imaging devices, including optical coherence tomography (OCT) [1], have allowed visualization of the diseased retina and pathologic processes underlying various ocular conditions. The OCT device provides detailed images, which allow layer-by-layer analysis of macular microstructures. This has proven extremely useful in evaluating various retinal diseases [2].

Common retinal features on OCT images include 3 highly reflective bands in the outer retina, which are used as markers of photoreceptor integrity. These linear structures represent the external limiting membrane (ELM), the inner segment ellipsoid (ISe), and the interdigitation zone (IZ) [3, 4] and are disrupted or absent in many central retinal functional disorders [5]. However, how to interpret OCT findings is still under debate [3]. For example, the ISe was previously called the inner segment/outer segment junction (IS/OS) and the IZ line was previously called the cone outer segment tips (COST) or outer segment-retinal pigment epithelium (RPE) interdigitation [4]. Thus, it is certain that image abnormalities reflect anatomical changes in photoreceptors, but how
these OCT characteristics correlate with photoreceptor anatomy remains unclear.

Retinitis pigmentosa (RP) and cone-rod dystrophy (CRD) belong to a set of hereditary diseases that affect photoreceptors. Retinitis pigmentosa is characterized by primary impairment of rod photoreceptors [6], but CRD is characterized by primary impairment of cone photoreceptors [7, 8]. In later stages of both diseases, both rods and cones degenerate, resulting in both central and peripheral visual dysfunction.

As expected by the pathology of the diseases, disruption or disappearance of the ELM, ISe, and/or IZ have been reported in eyes with these diseases e.g. in RP [9-12], cone dystrophy [13-17], and CRD [18]. In addition, a recent study suggested that the IZ line is useful in differentiating between different types of photoreceptor degenerations because cone photoreceptors are primarily impaired in CRD [19]. However, it is not known if changes of IZ line is specific to CRD because IZ appearance on OCT is sensitive to any kind of photoreceptor damage [20]. A previous study compared ISe status in eyes with CRD and eyes with RP. It was concluded that eyes with CRD are missing the foveal ISe more frequently [18]. Unfortunately, this result may have resulted from
differences in central retinal function between CRD and RP patients, so it is not clear if this difference is reflective of different disease processes.

In the present study, we use OCT to examine visual acuity-matched eyes with either CRD or RP. Specifically, differences in ELM, ISe, and IZ line status were investigated in hopes of determining if anatomical differences in rod-cone and cone-rod macular impairment exist.

**Methods**

All study procedures adhered to the tenets of the Declaration of Helsinki and the study protocol was reviewed and approved by the Institutional Review Board (IRB)/Ethics Committee of the Kyoto University Graduate School of Medicine. The IRB waived the need for written informed consent.

**Patient Characteristics**

We retrospectively reviewed the clinical records of consecutive CRD patients. All patients underwent comprehensive ophthalmic examinations, including visual acuity measurement, kinetic and static visual field testing, full-field electroretinography (ERG, recordings obtained following the 2008
recommendations of the International Society for Clinical Electrophysiology of Vision [21]), fundus photography, OCT, and slit-lamp biomicroscopy. The CRD diagnosis was made based on the presence of progressive visual acuity loss, photophobia, and reduced or extinguished photopic and flicker ERG amplitude. A family history of CRD or atrophic foveal changes, confirmed with fundus examination or OCT, supported the diagnosis. All included CRD patients had been examined using the Spectralis® spectral domain OCT (Heidelberg Engineering, Heidelberg, Germany). No patient had media opacities severe enough to interfere with OCT imaging.

To compare findings in CRD eyes with those of RP eyes, we included a group of visual acuity-matched RP patients who had been seen at our clinic. The diagnosis of rod-cone dystrophy was also made based on clinical presentation and patient symptoms including progressive visual acuity or visual field loss, night blindness, characteristic fundus appearance (e.g., bony spicule pigmentation), and reduced or extinguished scotopic ERG amplitude. To exclusively compare cone-rod and rod-cone dystrophies, patients with macular dystrophy and normal photopic and scotopic ERGs, despite fundoscopic macular degeneration, were excluded.
One RP patient was included for every CRD patient and when 2 or more visual acuity-matched RP patients were found, the one closest in age to the corresponding CRD patient was chosen. Data from the right eye of each patient was used, unless media opacity prevented good quality OCT images from being obtained.

*Clinical Characteristics*

The inheritance pattern of each patient was determined based on family history. Visual acuity was measured with Landolt C charts and converted to the logarithm of the minimum angle of resolution (logMAR) equivalent for analyses. Central retinal sensitivity was measured with the Humphrey field analyzer (Carl Zeiss Meditec, Tokyo, Japan) using the Swedish Interactive Threshold Algorithm Standard 10-2 program.

Optical coherence tomography had been performed on all patients. Horizontal scans centered on the fovea were reviewed by 2 independent examiners (EI, AO) for the presence/absence of foveal ELM, IS, and IZ lines. Examiners were masked to all other parameters and clinical measurements during evaluation. When interpretation discrepancies occurred, a third examiner
(KO) arbitrated. Central retinal thickness, defined as the distance between the inner surface of the internal limiting membrane and the outer border of the RPE, was manually measured.

Statistical Analyses

Statistical SPSS software (version 19, IBM Japan, Tokyo, Japan) was used to perform all statistical analyses. Data are presented as mean ± standard deviation, unless otherwise specified. Comparisons between groups were performed using unpaired t-tests or chi-square tests, as appropriate. Statistical significance was defined as $P < 0.05$. When multiple comparisons were performed, the Holm’s correction was applied and the significance level adjusted. This method modifies rejection criteria to control the overall probability of a type 1 error. First, P-values for each comparison were ordered. We then applied the rejection criteria $P \geq 0.05$ for the largest P-value, $P \geq 0.025$ ($0.050/2$) for the second largest P-value and so on.

Results

A total of 35 patients with CRD and 35 patients with RP were included in
analyses. Patient characteristics are summarized in Table 1. Because subjects were visual acuity-matched, no significant difference in visual acuity existed between the CRD and RP groups. Even though all efforts were made to also age-match the groups, RP patients (60.2 ± 10.7 years) were significantly older than CRD patients (51.7 ± 14.6 years, P = 0.010). The amplitude of ERG waveforms was also more severely impaired in RP patients than in CRD patients. Genetic screening had been previously performed in some CRD patients and revealed mutations of the \textit{ABCA4} gene in 5 patients, the \textit{GUCY2D} gene in 3 patients, the \textit{CRX} gene in 1 patient, and the \textit{CEP290} gene in 1 patient. In the RP group, 1 patient had mutations of the \textit{EYS} gene and 1 patient had a mutation in the \textit{RHO} gene.

Outer retinal status, determined on OCT images, is shown for each patient group in Table 2. The central retina was significantly thinner in CRD patients than in RP patients. In addition, CRD patients tended to be missing the ELM and ISe more frequently than RP patients, but this difference was not statistically significant. Interestingly, none of the CRD patients had an intact IZ line, but 20% of the RP patients did (P = 0.011). In addition, some CRD patients had a hyporeflective space beneath the fovea, which appeared similar to
subretinal fluid (Figure). This anomaly was previously named, “foveal cavitation” [22], and was present more often in CRD patients (25.7%) than in RP patients (5.7%, P = 0.045 but adjusted significant level should be 0.017). Though relatively large, this difference was not statistically significant after multiple testing corrections were applied.

Finally, the clinical characteristics between CRD patients with and without foveal cavitation were compared (Table 3). Interestingly, CRD patients with foveal cavitation tended to be younger than those without it and were more likely to have an intact ELM or ISe.

Discussion

In the present study, we showed that the IZ line on OCT images may be present in eyes with RP, but is generally not present in eyes with CRD. Additionally, approximately 25% of patients with CRD have foveal cavitation. These results support the idea that the IZ line reflects cone photoreceptor integrity and that foveal cavitation indicates cone-dominant photoreceptor loss.

The IZ line is vulnerable to damage and is disrupted in virtually every kind of macular diseases [5] [20]. Disruption of the IZ line has been reported both in
RP [12] and in CRD [19], but the difference between these retinal dystrophies is not known. The results of the current study showed that the IZ line is visible in some patients with RP, but not in any patients with CRD, even though patients had similar visual acuity. Considering that both diseases affect both cone and rod photoreceptors, and that the difference between them is cone-dominant or rod-dominant impairment, more frequent absence of the IZ line in eyes with CRD is likely attributable to predominantly cone impairment. This finding indicates that the cone photoreceptor outer segment/RPE interdigitation site is disrupted relatively early in the course of the CRD.

Yokochi et al. [18] previously compared macular structures in eyes with RP and CRD. They found that the ISe (or IS/OS) is absent in the fovea of patients with CRD. In contrast, we did not find a difference in ELM or ISe status between eyes with CRD and eyes with RP. This discrepancy may have been caused by differences in the 2 study populations. Mean logMAR visual acuity of RP patients in Yokochi et al.’s study [18] was -0.03, indicating a relatively early disease stage. Average logMAR visual acuity in our study was 0.84 in RP patients, indicating a much later disease stage. Therefore, it is likely that our patients had more severe damage to foveal structures than those in the previous
study. Additionally, the present study showed only minimal difference in foveal ELM and ISe status between RP and CRD patients. This result indicates that these structures may be less vulnerable to damage than the IZ line.

Focal loss of outer foveal reflectivity on OCT images, or foveal cavitation, has been reported in eyes with Stargardt disease, congenital achromatopsia, and cone dysfunction syndromes [16, 17, 23-25]. Subsequent reports have demonstrated that foveal cavitation is not specific to Stargardt disease or achromatopsia, and that it can be found in eyes with foveal cone impairment [22]. In the present study, 25.7% of CRD patients had this OCT finding, but it was only found in 5.7% of RP patients. This difference was not statistically significant after Holm’s correction was applied. Considering that the CRD and RP groups were visual acuity-matched and had statistically the same ISe status, foveal cavitation may specifically reflect predominant cone loss with relative rod preservation. The previous study suggested that structural support or tension is needed to have subretinal fluid remain unabsorbed [22]. Rod outer segments, which are longer than cone outer segments, might function as such a structural support. The loss of cone outer segments results in space without cellular material, which would likely appear as a hyporeflective space on OCT images. This hypothesis is
consistent with the relatively high frequency in which foveal cavitation occurs in patients with congenital achromatopsia, Stargardt disease, and cone dysfunction syndrome [16, 17, 22-25]. With impairment of both rod and cone photoreceptors, the retina would be uniformly thinned rather than having cavitation. Further exploration of the foveal cavitation phenomenon in other conditions is needed to better understand its origins and what it anatomically represents.

Interestingly, patients who had foveal cavitation were younger and had better preservation of both the ELM and ISe. These results might indicate that foveal cavitation only occurs temporarily and is unique to a specific disease stage. It likely appears when cone photoreceptors are damaged and outer segment loss has occurred. As the ISe and, subsequently, the ELM become obscured, further photoreceptor impairment occurs and foveal cavitation disappears. Longitudinal studies are needed to determine the time course and disease stage at which cavitation appears and disappears.

Our study had several limitations. Although we made all attempts to visual acuity-match and age-match RP patients to CRD patients, CRD patients were, on average, younger than RP patients. This age discrepancy reflects the differences in disease course. Visual acuity is relatively preserved in patients
with RP until the later stages of the disease. Additionally, cone and rod responses, as measured with ERG, were significantly better preserved in eyes with CRD than in eyes with RP. Therefore, RP patients with the same visual acuity as CRD patients would be in later disease stages than corresponding CRD patients. If both visual acuity- and age-matched comparisons were possible, study results may have differed.

Another study limitation is inclusion bias. We only included patients who were diagnosed with these diseases, which may have excluded patients with less distinctive disease presentation. Thus, our results are only applicable to patients with relatively typical RP and CRD cases and not the entire disease cohort.

In conclusion, we showed that ELM and ISel status are not different between RP and CRD patients when visual acuity is matched. Patients with CRD almost never have an intact IZ line and sometimes show foveal cavitation on OCT images at a relatively early disease stage. These findings may improve our understanding of how photoreceptor degenerations are represented on OCT images.
