(Received 27 June 2013; revised manuscript received 24 September 2013; published 13 December 2013)

To examine the validity of the scenario of the deconfined critical phenomena, we carry out a quantum Monte Carlo simulation for the SU($N$) generalization of the Heisenberg model with four-body and six-body interactions. The quantum phase transition between the SU($N$) Néel and valence-bond solid phases is characterized for $N = 2$, 3, and 4 on the square and honeycomb lattices. While finite-size scaling analysis works well up to the maximum lattice size ($L = 256$) and indicates the continuous nature of the phase transition, a clear systematic change towards the first-order transition is observed in the estimates of the critical exponent $\gamma \approx 1/\nu$ as the system size increases. We also confirm the relevance of a squared valence-bond solid field $\Psi^2$ for the SU(3) model.

The definition of the complex order parameter $P_{ij}$ as $P_{ij} = \frac{1}{N} \sum_{\alpha=1}^N \sum_{\beta=1}^N e^{i Q S_{\beta \alpha} f_{ij}}$. We adapt the fundamental representation on one sublattice and the conjugate representation on the other sublattice. Our QMC simulation is based on the world-line representation with the loop update and the honeycomb lattice, respectively. The inset of Fig. 2 shows the two-point correlation of the projection operator, respectively. According to Read and Sachdev, the complex VBS operator $\Psi$, where $\psi_\alpha$ is the meron (half-skyrmion) annihilation operator with $\eta_\mu$ being the total number of sites, which agrees with the staggered magnetization in the SU(2) case. We try to fit the obtained estimates of the magnetization to the FSS form $(m^2) = L^{-2\eta_\mu} \tilde{\chi}(L')$ with $t = q - q_c$ and $y = 1/v$, where $q = Q/(J + Q)$. Figure 2 shows the result of the fitting with limited system sizes $L \leq 96$ in the case of the SU(3) model on both the square and honeycomb lattices. (This system-size range is simply due to the fact that the largest system on the honeycomb lattice studied here is $L = 96$.) The values used for Fig. 2 are $q_c = 0.3353$ for the square lattice and $q_c = 0.2036$ for the honeycomb lattice. The same values of exponents $y = 1.87$ and $2\eta_\mu = 1 + \eta_\mu = 1.40$ are used for both lattices. The horizontal and vertical axes for the honeycomb lattice are rescaled to match those of the square lattice. Note that not only do different system sizes fall on the same curve, but also two lattices with different lattice rotational symmetries also collapse on the same curve. Since the symmetry that is broken at the transition point is different in the two cases, a different universality class may be naturally expected. Therefore, this universal behavior supports the DCP scenario. From a similar analysis we obtain reasonably good FSS plots for SU(2) and SU(4) models as well. The data for the SU(2) model produce the best fitting with $y = 1.78$ and $2\eta_\mu = 1.289$ at $q_c = 0.9585$ and $q_c = 0.5440$ for the square and the honeycomb lattice, respectively. Note here that we use data for $L \leq 128$ and 96 for the square and honeycomb lattices, respectively. These values are consistent with a recent parallel work that reports the DCP on the SU(2) honeycomb lattice model. The inset of Fig. 2 shows the two-point correlators $C_{\alpha}(R_{ij}) \equiv \frac{1}{N} \sum_{\beta} (m_{i\alpha} m_{j\beta})$ as a function of the distance for the SU(3) models on the square lattice of $L = 256$. The critical value estimated from the data of $L = 256$ is $q_c = 0.3343(1)$. While it is slightly smaller than the one quoted above for smaller systems, the correlation decay up to $R \sim 24$ lattice units is not so sensitive to $q$ and is well characterized by the exponent obtained above from the squared magnetization.
POSSIBILITY OF DECONFINED CRITICALITY IN SU(…)

FIG. 3. (Color online) The FSS plot for the squared amplitude of total VBS order for the SU(3) J-Q model on the square and the honeycomb lattices with the system size being restricted to \( L \leq 96 \). We set the scaling factors \( A = 2.422 \) and \( B = 0.6388 \) for the honeycomb lattice. Inset: The two-point correlation function of VBS order for the SU(3) models on a square lattice of \( L = 256 \) as a function of the distance at various \( q \) near the critical point. The straight line corresponds to the estimate for \( 2x_\Psi \) obtained from the squared amplitude of the total VBS order.

\( q_c = 0.0805 \) and \( q_c = 0.0150 \) for the square and the honeycomb lattice, respectively. The two-point correlator of the local VBS order parameter \( C_{\Psi R}(R_{ij}) \equiv \langle \Psi_i^* \Psi_j \rangle \) is also shown in the inset of Fig. 3. Again, we observe the consistency between the estimates of the critical indices obtained from \( \langle |\Psi_i^\gamma|^2 \rangle \) and \( C_{\Psi} \).

Systematic size dependence. The strongest skepticism concerning the critical nature of the phase transition comes from the argument\(^{16} \) that the true nature of the transition is revealed only in a very long range behavior, and that the previously attainable system size might not have reached that regime. In order to see the systematic trend as we go to a larger length scale, we apply the FSS analysis for quadruplets of the system sizes from \( L_{\text{max}}/3 \) to \( L_{\text{max}} \) such as \( [32, 48, 64, 96] = L_{\text{max}} \), and systematically change the value of \( L_{\text{max}} \). In Fig. 4, we plot the \( L_{\text{max}} \) dependence of these estimated scaling dimensions. We use the same value of \( q \) and \( y \equiv 1/\nu \) for both the magnetization and the VBS order parameter. (This time we have lifted the restriction that \( y \) should be independent of the lattice.) As is evident, for the SU(2) and the SU(3) models, there is a systematic trend of increasing \( y \) as a function of \( L_{\text{max}} \). Whether it will eventually reach the value \( y = d + 1 = 3 \), the value expected for the first-order transition, cannot be judged from the present data. We should note here that large values of \( y \) do not necessarily suggest the first-order transition since the \( 1/N \) expansion\(^{25} \) also predicts large values for the DCP fixed point for small \( N \). The systematic decrease in the effective values of the scaling dimensions \( 2x_\Psi \) and \( 2x_\Psi \) is not as strong as \( y \), while both of them should converge to zero if the transition is of the first order. The size dependence of the SU(4) model looks somehow different from those of the other cases. The systematic drifts in the critical indices are much weaker.

Higher power of local VBS order. We can directly estimate the order of the quantum VBS phase transition through the relevance or irrelevance of the higher power of the local VBS order parameter \( \Psi^q \) with \( q \geq 2 \). In order for the quantum transition on the square lattice to be of second order, \( \Psi^4 \) must be irrelevant since this field is naturally included in the Hamiltonian for the lattice with \( Z_4 \) symmetry. Similarly, the relevance or irrelevance of \( \Psi^3 \) and \( \Psi^2 \) is crucial, respectively, to the transition in the honeycomb lattice and to that in the square lattice with strong spatial anisotropy.\(^{26,27} \) The straightforward definition of \( \Psi^q \) is not suitable here because of the discrete nature of the present \( \Psi \) in contrast to its counterpart in the continuous field theory. Instead, we define the block-averaged order parameter \( \Psi_i \equiv \frac{1}{b} \sum_{j \in \Omega_b(i)} \Psi_j \), where \( \Omega_b(i) \) is the region of a square with the linear scale \( b \) centered at \( i \). In Fig. 5, the two-point correlator for \( q = 2 \), \( C_{\Psi^2}(R_{ij}) \equiv \langle (\Psi_i^*)^2 (\Psi_j)^2 \rangle \), is plotted against the distance. From the figure, we estimate the scaling dimension of squared VBS order as \( 2x_\Psi \approx 4.0 \), or \( y_{\Psi^2} \approx 1.0 > 0 \), i.e., the skyrmion-pair operator is relevant at the deconfined critical point. This result shows that even if the DCP scenario is the correct...

FIG. 4. (Color online) The estimate of the scaling dimensions \( y \equiv 1/\nu \) and \( 2x \) for the SU(\( N \)) model on the square and honeycomb lattices as a function of the system size used in the FSS. At \( L_{\text{max}} = 256 \), \( q_c = 0.9568(2) \), 0.3343(1), and 0.0814(3) for \( SU(N = 2, 3, 4) \) models on a square lattice, respectively.

FIG. 5. (Color online) The two-point correlation function of the square of block-averaged order parameter \( \langle \Psi \rangle^2 \) for the SU(3) models as a function of the distance at \( q = 0.3343 \), which is the critical point estimated from the data of \( L \leq 256 \). The block size \( b \) is 8.

FIG. 2. (Color online) (a) Square: \( L = 32 \), \( 48 \), \( 64 \), \( 96 \). Honeycomb: \( L = 36 \), \( 72 \), \( 96 \).
description of the Néel-VBS quantum phase transition, it cannot take place in the SU(3) $J$-$Q$ model with only $Z_2$ lattice rotational symmetry, where the model intrinsically contains the relevant perturbation $\Psi^2$. It follows, for example, that the quasi-one-dimensional biquadratic Heisenberg model should not have a DCP critical point.\textsuperscript{26} In previous work,\textsuperscript{26} the numerical results were analyzed mainly with the assumption of the criticality. This was partially due to the very slow onset of the order parameter as a function of the system size and the absence of a clear discontinuity, particularly for small systems. However, a trend similar to the one described above was already detected there; the large estimates of $\gamma \equiv 1/v$ [e.g., $\gamma = 2.5(2)$ for the VBS order parameter, and $\gamma = 2.9(2)$ for the magnetization order parameter]. The discontinuous nature of the spatially anisotropic SU(3) model is also consistent with the conclusion of a recent study based on the FSS analysis for the same model.\textsuperscript{28} In the cases of $q \geq 3$, the scaling dimension is probably larger than that of $q = 2$. However, we have not succeeded in reliably estimating them due to relatively large statistical noises.

Conclusions. We have presented a series of numerical results on the SU($N$) $J$-$Q$ models on two lattices, square and honeycomb ones. Up to the system size explored in the present study, all the scaling analyses work fine as long as the range of the system size is not broad. Based on the assumption of the criticality, we have estimated various critical indices. The estimates obtained with different quantities on different lattices are consistent with each other. In addition, the agreement between the numerical estimates of the critical exponents $x_{\Psi}$ and $x_{\Phi}$ with the $1/N$ expansion\textsuperscript{25} is still good even after the present updates of the former based on the largest systems. These pieces of evidence are consistent with the DCP scenario. However, the previous estimate of $\gamma$ in Ref. 13 had to be considerably shifted beyond the error estimated then. This trend is systematic; for the SU(2) and SU(3) cases at least, the estimate increases as the system becomes larger and it seems to continue to grow beyond the largest estimate obtained in the present work. Because of these observations, we have to keep the possibility of a first-order transition still open. If the transition is of first order, the question will be about the reason for the apparent universal behaviors. It would be rather difficult to explain the observed behaviors unless the DCP fixed point exists close to the renormalization group trajectory of the present model, even if it may not be the governing fixed point. Whether the difference between SU(4) and the other two cases persists for larger systems is also an important question and requires further studies.

Acknowledgments. The computation in the present work was executed on computers at the Supercomputer Center, ISSP, University of Tokyo, and also on the K computer at the RIKEN AICS (Project No. hp120283).
