Efficient near-infrared up-conversion photoluminescence in carbon nanotubes

Naoto Akizuki¹, Shun Aota¹, Shinichiro Mouri¹, Kazunari Matsuda¹ & Yuhei Miyauchi¹,²,³

Photoluminescence phenomena normally obey Stokes’ law of luminescence according to which the emitted photon energy is typically lower than its excitation counterparts. Here we show that carbon nanotubes break this rule under one-photon excitation conditions. We found that the carbon nanotubes exhibit efficient near-infrared photoluminescence upon photoexcitation even at an energy lying >100–200 meV below that of the emission at room temperature. This apparently anomalous phenomenon is attributed to efficient one-phonon-assisted up-conversion processes resulting from unique excited-state dynamics emerging in an individual carbon nanotube with accidentally or intentionally embedded localized states. These findings may open new doors for energy harvesting, optoelectronics and deep-tissue photoluminescence imaging in the near-infrared optical range.

Photoluminescence phenomena normally obey Stokes’ law of luminescence, which states that the emission light wavelength (energy) is typically longer (lower) than its excitation counterpart. Up-conversion (or anti-Stokes) photoluminescence violates the Stokes’ law of luminescence owing to additional energy gain induced by multiple photon or thermal (phonon) energy absorption. This unique photon up-conversion phenomenon only occurs efficiently in certain materials such as rare-earth-doped materials and some organic dyes by virtue of their specific electronic structures. Its potential usefulness in various applications such as photovoltaic energy conversion, photoluminescence bio-imaging, displays, lasers and optical refrigeration of solids has attracted growing interest in recent years. However, especially in the near-infrared optical range, limitations in materials and combinations of excitation and emission photon energies available for efficient photon up-conversion have reduced its compatibility with a wide range of applications.

Here, we demonstrate that carbon nanotubes are new up-conversion materials. Single-walled carbon nanotubes (hereafter referred to as carbon nanotubes) consist of graphene sheets rolled up into quasi-one-dimensional tubular structures with diameters of the order of 1 nm. Depending on the rolling-up direction and their diameter defined by two indices \((n, m)\), nanotubes act as direct gap semiconductors with band gaps of the order of 1 eV and emit photoluminescence in the near-infrared optical range because of recombination of excitons (electron and hole pairs bound via attractive Coulomb interactions). The first observation of efficient Stokes photoluminescence from individual carbon nanotubes, numerous distinctive luminescence properties of nanotubes and their applications have been uncovered over the past decade. However, this report reveals an additional remarkable characteristic of carbon nanotubes as photoluminescent materials.

Results

Optical imaging of the up-conversion light emission. Figure 1a shows an optical image of photoluminescence from (6,5)-rich carbon nanotubes dispersed in \(\text{D}_2\text{O}\) at an excitation energy of 1.13 eV. The emission peak detected at 1.26 eV upon excitation at 2.18 eV corresponds to the first sub-band exciton energy \(E_{22}\) of (6,5) nanotubes. The photoemission spectrum obtained at an excitation energy of 1.13 eV displays 14,15 laser excitation. The grey curve shows control data obtained for a nano-tube-free surfactant solution excited at 1.13 eV. The emission peak at 1.26 eV upon excitation at 2.18 eV (resonant with the second sub-band exciton energy \(E_{22}\) of (6,5) nanotubes) corresponds to the photoluminescence induced by exciton recombination in the first sub-band \((E_{21})\) of (6,5) nanotubes. The photoemission spectrum obtained at an excitation energy of 1.13 eV exhibited a peak at ca. 1.26 eV. The similar peak energies for excitation energies of 1.13 and 2.18 eV indicate that the photoemission mainly originates from (6,5) nanotubes.

Excitation power dependence. The excitation power density dependence was examined to clarify the origin of the observed...
up-conversion photoemission. The spectral shape hardly changed with excitation power density variations (Fig. 2b). Figure 2c shows the up-conversion photoemission intensity as a function of excitation power density, revealing a weak sublinear dependence between these parameters. These observations exclude any possible photoemission induced by multiple-photon absorption (coherent or incoherent) or Auger recombination-mediated up-conversion as origins for the observed phenomena because these mechanisms usually display a superlinear (quadratic or more) excitation power dependence.

**Excitation photon energy dependence.** Next, the excitation photon energy dependence of the up-conversion photoemission spectra was evaluated (Fig. 2d). The up-conversion intensity strongly depended on the excitation photon energy (wavelength) but spectral shape and peak positions remain nearly intact upon excitation photon energy variations. This observation rules out the possibility that the up-conversion photoemission results from anti-Stokes Raman scattering because Raman processes induce clear peak shifts according to excitation energy changes. The exclusion of these potential processes suggests that the observed up-converted photoemission is attributable to photo-luminescence induced by one-photon absorption followed by an internal excitonic up-conversion process in a carbon nanotube. Therefore, the observed phenomena are referred to as up-conversion photoluminescence in the remainder of the manuscript. Let us now consider the mechanism that governs this efficient excitonic up-conversion. The excitation photon energy dependence of the up-conversion intensity may provide a clue to the mechanism. Figure 2e compares the observed up-conversion photoluminescence intensity (red circles, from spectra in d) as a function of excitation photon energy, plotted together with normal photoluminescence spectrum (black curve) obtained at an excitation energy of 2.18 eV. The threshold excitation photon energy required to achieve an observable up-conversion photoluminescence reaching ca. 1.3 eV amounted to 1.03–1.08 eV. A dashed line corresponds to an intermediate state in the up-conversion process.

**Temperature dependence.** The threshold energy gain close to the maximum optical phonon energy (~0.2 eV) in carbon nanotubes and increasing up-conversion efficiency for smaller energy gain imply that phonon-assisted processes may induce internal up-conversion in carbon nanotubes. Therefore, temperature-dependent studies on the up-conversion photoluminescence were conducted. Figure 3a compares up-conversion photoluminescence intensities at 297 and 281 K at an excitation energy of 1.13 eV.
sensitivity to small temperature variations and increased with increasing temperature. Figure 3b shows the up-conversion (red open circles) and normal photoluminescence intensities (black open circles) as functions of temperature. Up-conversion and normal photoluminescence intensities displayed opposite trends with respect to temperature (Fig. 3b). The up-conversion photoluminescence intensity increased, whereas its normal counterpart slightly decreased when the temperature increased.

Figure 3c shows an Arrhenius plot of the up-conversion intensity $I_{\text{UCPL}}$ divided by the normal photoluminescence intensity $I_{\text{PL}}$ at each temperature. The solid line in Fig. 3c represents the Arrhenius equation $I_{\text{UCPL}} / I_{\text{PL}} = \exp(-E_a/k_B T)$ where $E_a$, $k_B$, and $T$ are the activation energy, Boltzmann constant (and temperature) for an $E_a$ value of 120 meV. (See also Supplementary Fig. 2 for data obtained at an excitation energy of 1.08 eV.) The experimental trend was well reproduced with an $E_a$ value closely matching the typical energy gain (120–130 meV) at an excitation energy of 1.13 eV, strongly suggesting that the internal exciton up-conversion originates from phonon absorption processes in carbon nanotubes, rather than other possible processes such as triplet–triplet annihilation.$^{30}$ Note that the activation energy $E_a$ nearly equal to the energy gain indicates one-step up-conversion via absorption of an optical phonon with much higher energy ($\sim$100–200 meV) than $k_B T$ ($\sim$26 meV), distinct from common thermal activation process in which the additional energy is mainly provided by absorption of multiple phonons with energy comparable to or lower than $k_B T$.

Intermediate states in up-conversion processes. Now that the up-conversion photoluminescence has been clearly attributed to phonon-assisted processes, the reason for the efficient phonon-assisted up-conversion with an energy gain reaching 5–10 $k_B T$ needs to be elucidated. The weak sublinear dependence of the up-conversion photoluminescence intensity on the excitation power density (Fig. 2c) may provide insights into this anomalous phenomenon. The sublinear dependence implies the existence of an intermediate state, but finite lifetime causing state-filling-induced saturation effect. Because it lies at lower energy than the $E_{11}$ free exciton state, this state may be a mid-gap localized state$^{31–34}$ unintentionally generated in carbon nanotubes during sample preparation because some types of these states$^{32–36}$ are optically active and can be photoexcited directly by near-infrared photons.

To test this hypothesis, localized states were intentionally embedded in carbon nanotubes by chemical treatments$^{32–34}$, and up-conversion photoluminescence changes were examined. Carbon nanotubes with oxygen- and sp$^3$-defect-derived optically active localized (zero-dimensional (0D)-like) states were prepared according to procedures originally developed by Ghosh et al.$^{32}$ and Piao et al.$^{34}$ with some modifications in selections of chemicals and experimental parameters, respectively (Methods section). Figure 4a,f compare the normal photoluminescence spectra of as-dispersed (black curves) and sp$^3$-defect (red curve) or oxygen-doped (blue curve; hereafter referred to as 0D-doped) carbon nanotubes. A relatively broad and intense photoluminescence band emerged around 1.1 eV after chemical treatment, whereas the original $E_{11}$ photoluminescence intensities decreased only slightly for 0D-doped nanotubes. Figure 4b–e,g–j show up-conversion photoluminescence spectra of as-dispersed (black curves) and 0D-doped carbon nanotubes (coloured curves) excited at 1.13, 1.08, 1.03 and 1.00 eV, respectively. Note that the 0D-doped nanotubes displayed a considerably enhanced up-conversion photoluminescence intensity compared with their as-dispersed counterparts regardless of origins of the localized states.

Figure 4k,l compare the excitation energy-dependent up-conversion photoluminescence intensities of as-dispersed and 0D-doped nanotubes. The up-conversion photoluminescence intensity increased dramatically at the excitation energy of 1.08 eV for 0D-doped nanotubes. Because this energy closely matched the photoluminescence peak energy of the localized excitons (Fig. 4a,f), this enhancement is attributable to exciton up-conversion from the additional localized states. The temperature (Supplementary Fig. 3) and the excitation power density dependences (Supplementary Note 2 and Supplementary Fig. 4) of the up-conversion photoluminescence were also assessed for the 0D-doped nanotubes. The results were similar to those obtained for as-dispersed nanotubes. This strongly suggests that the embedded localized states act as intermediate states in up-conversion processes. Moreover, the strong enhancement of the up-conversion photoluminescence achieved by simple chemical treatments is attractive for their applications as up-conversion phosphors.

Discussion
We deduced the up-conversion quantum yield of the localized excitons to the free excitons using the difference between up-conversion photoluminescence intensities before and after intentional localized state doping (see Supplementary Discussion and Supplementary Fig. 9 for details). It was of the order of $10^{-1}$ for an energy gain of 120 meV even at room
up-conversion photoluminescence of the (6,5) carbon nanotubes with the inverted excitation (in the NIR II range) and emission (<1,000 nm, so-called NIR I range) wavelengths may solve this problem and facilitate deep-tissue bio-imaging by taking advantage of the large penetration depth of NIR II photons and common silicon-based image sensors (Supplementary Notes 3–5 and Supplementary Figs 5–8). Because up-conversion occurs as a one-photon process in carbon nanotubes, it does not require costly ultrafast high-power lasers and high-density excitation conditions, unlike conventional multi-photon excitation imaging. Furthermore, up-converted photocarriers in carbon nanotubes may be directly extracted as electronic current by configuring photovoltaic devices because of their quasi-one-dimensional structures. Therefore, these findings may also lead to new routes for optoelectronics and heat and photon harvesting below the optical gap in the near-infrared region.

Methods

Sample preparation. (6,5)-rich CoMoCAT carbon nanotubes (Southwest Nanotechnologies, USA) were dispersed in D2O in the presence of 0.2% (w/v) sodium dodecyl benzene sulfonate under moderate bath sonication for 60 min and vigorous sonication using a tip-type sonicator for 40 min before centrifugation at an acceleration of 130,000g for 4 h (ref. 19). For the experiments shown in Fig. 4, additional localized states were embedded in carbon nanotubes by atomic oxygen32 or sp3-defect doping34 that reduce the band gap and exciton energy locally. Oxygen- and the sp3-defect-doped carbon nanotubes were prepared according to procedures originally developed by Ghosh et al.32 and Piao et al.34, respectively, with different chemical and experimental parameter selections32–34. In brief, the isolated nanotube dispersion was combined with a small amount of D2O containing dissolved ozone and left under the illumination of a desk lamp (ca. 5 mW cm−2) overnight, allowing moderate atomic oxygen doping to generate sparse oxygen-derived local states. To achieve sp3-defect doping, the nanotube dispersion was combined with a small amount of D2O-containing dissolved organic 4-benzaldehyde and tetramethylammonium salts32 and left in the dark for at least 10 days, allowing moderate sp3-defect doping in carbon nanotubes to generate sparse sp3-defect-derived localized electronic states. Optical absorption spectra of these samples are presented in Supplementary Fig. 1.

Optical measurements. Optical measurements were conducted using a broadband supercontinuum white light source (Fianium, SC450) for excitation. Incident light wavelengths were selected using a monochromator for normal Stokes emission measurements and optical filters for up-conversion photoemission measurements. The typical excitation band width was 10 nm for spectroscopic measurements and any unwanted stray light was carefully removed using multiple optical filters. Normal photoluminescence measurements were performed using monochromatic light at a wavelength of 568 nm (2.18 eV) that matches the E22 optical resonance in (6,5) carbon nanotubes for photoexcitation. The optical image showing up-conversion photoemission phenomena (Fig. 1) was taken using an electron multiplying charge coupled device (EMCCD) camera (Princeton Instruments, ProEM). The microscopic up-conversion photoemission imaging of an individual carbon nanotube was performed using an inverted microscope and a 1.4 NA, ×100 objective under epi-illumination of the near-infrared incident light (1.075–1.125 nm, approximate power density of 4 kW cm−2). For the microscopic imaging, the individually dispersed nanotubes were immobilized using an agarose gel matrix17. During spectral measurements shown in Figs 2–4, the nanotube dispersion was set in a quartz cell with optical path of 1 mm. Incident light was focused on the sample in the quartz cell as a 4–6-μm spot using an achrhomatic lens, and light emitted from the samples was collected by an achrhomatic lens and transferred to a confocal optical set-up. The near-infrared photoemission was recorded using a liquid nitrogen cooled Si-CCD or an InGaAs array detector. Detection sensitivity variations were corrected using a standard light source (Ocean Optics, LS-1). The spectral resolution typically equaled 2 nm. We used spectral-integrated intensity for the analyses of the
