The multiple bonding in heavier group 14 element alkene analogues is stabilized mainly by dispersion force effects†

Jing-Dong Guo,a David J. Liptrot,b Shigeru Nagase*a and Philip P. Power*b

The structures and bonding in the heavier group 14 element olefin analogues \([\text{E} \{\text{CH(SiMe}_3\text{)}_2\}_2\] and \([\text{E} \{\text{SiMe}_3\}_2\}]_2\] (E = Ge, Sn, or Pb) and their dissociation into \([:\text{E} \{	ext{CH(SiMe}_3\text{)}_2\}]_2\] and \([:\text{E} \{\text{SiMe}_3\}_2\}]_2\] monomers were studied computationally using hybrid density functional theory (DFT) at the B3PW91 with basis set superposition error and zero point energy corrections. The structures were reoptimized with the dispersion-corrected B3PW91-D3 method to yield dispersion force effects. The calculations generally reproduced the experimental structural data for the tetraalkyls with a few angular exceptions. For the alkyls, without the dispersion corrections, dissociation energies of \(-2.3\) (Ge), \(+2.1\) (Sn), and \(-0.6\) (Pb) kcal mol\(^{-1}\) were calculated, indicating that the dimeric E–E bonded structure is favored only for tin. However, when dispersion force effects are included, much higher dissociation energies of 28.7 (Ge), 26.3 (Sn), and 15.2 (Pb) kcal mol\(^{-1}\) were calculated, indicating that all three E–E bonded dimers are favored. Calculated thermodynamic data at 25 °C and 1 atm for the dissociation of the alkyls yield \(\Delta G\) values of 9.4 (Ge), 7.1 (Sn), and \(-1.7\) (Pb) kcal mol\(^{-1}\), indicating that the dimers of Ge and Sn, but not Pb, are favored. These results are in harmony with experimental data. The dissociation energies for the putative isoelectronic tetraamido-substituted dimers \([\text{E} \{\text{N(SiMe}_3\text{)}_2\}_2\}]_2\] without dispersion correction are \(-7.0\) (Ge), \(-7.4\) (Sn), and \(-4.8\) (Pb) kcal mol\(^{-1}\), showing that the monomers are favored in all cases. Inclusion of the dispersion correction yields the values 3.6 (Ge), 11.7 (Sn), and 11.8 (Pb) kcal mol\(^{-1}\), showing that dimerization is favored but less strongly so than in the alkyls. The calculated thermodynamic data for the amido germanium, tin, and lead dissociation yield \(\Delta G\) values of \(-12.2\), \(-3.7\), and \(-3.6\) kcal mol\(^{-1}\) at 25 °C and 1 atm, consistent with the observation of monomeric structures. Overall, these data indicate that, in these sterically-encumbered molecules, dispersion force attraction between the ligands is of greater importance than group 14 element–element bonding, and is mainly responsible for the dimerization of the metalanediyl’s species to give the dimetallenes. In addition, calculations on the non-dissociating distannene \([\text{Sn} \{\text{SiMe}_3\text{Bu}_2\}_2\}]_2\] show that the attractive dispersion forces are key to its stability.

Introduction

The synthesis of the lower valent group 14 element dialkyls \([:\text{E} \{\text{CH(SiMe}_3\text{)}_2\}]_2\] (E = Sn and Pb) in 1973 and the corresponding isoelectronic amido derivatives: \([\text{E} \{\text{N(SiMe}_3\text{)}_2\}_2\}]_2\] (E = Ge, Sn, and Pb) in 1974 were landmark events in the evolution of modern main group chemistry. The alkyl derivatives in particular were to exert a great influence on the perception of bonding between heavier main group elements because of their unprecedented structures and chemical behavior. Both the amides and alkyls were shown to exist as monomers in benzene solution and in the vapor phase. But whereas the amides remained monomeric as solids, the alkyl derivatives displayed unusual E–E bonded dimeric structures in the solid state. Although they are heavier congeners of substituted ethylenes, their group 14 atoms were found to have non-planar coordination, and the structures displayed a centro-symmetric trans-
pyramidalized (or folded) configuration (Fig. 1a), as well as E–E bond lengths that did not display the extent of shortening expected for double bond formation.\textsuperscript{8–11} The original interpretation of the (at the time) peculiar E–E bonding was based on either a double donor–acceptor bond (Fig. 1b) or a valence bond resonance structure (Fig. 1c). The bonding can be viewed also in terms of a pseudo (also called 2\textsuperscript{nd}-order) Jahn–Teller mixing\textsuperscript{12,13} of the \(\pi\)-bonding and \(\sigma^*\) levels which occurs upon a trans-bending distortion (\textit{i.e.} a vibration) of the E–E frameworks. The mixing of a bonding and antibonding orbital generates a molecular orbital with lone-pair character, and hence a pyramidalized coordination for E. This interaction takes place more readily in the heavier main group element derivatives because the bonds become increasingly long (weaker) as a result of larger Pauli repulsions between core electrons as the group is descended. Consequently, the energy difference between the \(\sigma^*\) \textit{and} \(\pi\) orbitals also decreases, and hence the extent of their interaction increases. The \textit{trans}-folding, which weakens the E–E bond, is often sufficient to cause dissociation of the double bond of the heaviest tin and lead species to two monomeric \textit{amidalized} coordination for E. This interaction takes place involuntarily in the association of sterically crowded phosphinyl and arsinyl \textit{E} bonded dimers. The calculations without the inclusion of dispersion force interactions between the \textit{C–C} bonded, less hindered, unsubstituted species \{E\}(=Ge, Sn, or Pb) as well as the corresponding E–E bonded dimers. The calculations without the inclusion of dispersion force effects revealed that the E–E bonded energies are low for the tetraalkyls, and insufficient to stabilize their dimeric structures under ambient conditions. In contrast, the inclusion of dispersion force resulted in large increases in the binding energies. Application of the same protocols to the amido compounds also afforded lower binding energies that are insufficient to sustain the dimeric structures under ambient conditions.

**Experimental section**

**Computational methods**

All calculations were carried out using the Gaussian 09 program.\textsuperscript{36} Geometry optimization was performed with hybrid density functional theory (DFT) at the B3PW91 (ref. 37) level by using the 6-311+G(2d) basis set for Ge, the \{433311/433111/43\} basis set augmented by two d polarization functions (d exponents 0.253 and 0.078) for Sn,\textsuperscript{38} the SDD basis set and its effective core potential for Pb,\textsuperscript{39} and the 6-31G(d,p)\textsuperscript{34–39} basis set for other atoms. In order to estimate the dispersion effects, geometries were reoptimized with the dispersion-corrected B3PW91-D3 method.\textsuperscript{40} Geometry optimization was also performed at the B97-D3 level.\textsuperscript{41} Single-point MP2 (second-order Møller–Plesset perturbation theory)\textsuperscript{42} energy calculations were performed on B3PW91-D3 optimized geometries. The basis set
superposition errors (BSSE) were estimated with the counter-
poise method. Enthalpy (H), entropy (S), and free energies (G)
as well as zero point energies (ZPE) were estimated using
calculated harmonic vibrational frequencies and BSSE cor-
rected energies.

Results and discussion

Computational data for the alkyl monomers and dimers,
E{CH(SiMe3)2}2 and [E{CH(SiMe3)2}2]2 (E = Ge, Sn, or Pb)
The calculated structural parameters at various levels of opti-
ization for the alkyl-substituted germanium, tin, and lead
monomers and dimers are presented in Table 1 and 2 respec-
tively. The E{CH(SiMe3)2}2 (E = Ge or Sn) monomers have the
syn, syn orientation of the –CH(SiMe3)2 alkyl groups in the gas
phase, as shown in Fig. 2a. At present, no gas phase electron
diffraction data are available for the Pb{CH(SiMe3)2}2 monomer.
However, in Table 1 we have given the experimental parameters
for Pb{CH(SiMe3)2}2, derived from a syn, syn Pb{CH(SiMe3)2}2 unit
within the [Pb{CH(SiMe3)2}2]2 (ref. 11) ‘dimer’. In the X-ray
structures of the germanium and tin crystalline dimers the
E{CH(SiMe3)2}2 (E = Ge or Sn) *18* units have a syn, anti confor-
mation, as shown in Fig. 2b. In contrast, the Pb{CH(SiMe3)2}2
units within the lead ‘dimer’ have the aforementioned syn, syn
configuration, as shown in Fig. 2c, i.e. the same configuration
as those experimentally observed for the germanium and tin dia-
alkyl monomers in the gas phase.18 The calculated bond lengths
and angles are generally close to those observed experimentally.

This statement is particularly true for the X-ray crystal struc-
tures of the germanium and tin dimers, where the experimental
structural parameters and E–E bond lengths (Ge–Ge = 2.347(2)
Å; Sn–Sn = 2.768(1) Å19) are reproduced with good accuracy.

Exceptions to this generalization involve the calculated torsion
angles between the methane C–H bonds and the central EC2
(E = Ge or Sn) plane in the germanium and tin monomers, and
the C–Ge–C angle in the germanium monomer, which is
somewhat high. For the torsion angle in the germanium and tin
monomers, the discrepancy is almost 20° in the germanium
and 6°–8° in the tin monomer. Unfortunately, in the monomic
structures which are measured from GED (gas electron differ-
raction) data, no standard deviations were given. However,
standard deviations of 2° were listed for the EC2 angle, and it is
reasonable to suppose the standard deviation for the torsion
angle for the methane C–H bonds would be larger than this value.
We replicated the optimization with the HCECH torsion
angles fixed at the experimental values of 2° (E = Ge) and 15°
(E = Sn). As shown in Table S1,† this increased the binding
energy by 10.7 kcal mol⁻¹ for Ge, but only 2.5 kcal mol⁻¹ for tin.

Thus, the HCECH torsion angle has significantly larger effect in
the germanium dimer, consistent with its more sterically-con-
gested structure. It is worthwhile to recall that the calculations
on the dimers are for the molecules in isolation (i.e. in the gas
phase), and take no account of the effects of neighboring
molecules (i.e. packing forces), which can also be expected to
exert some effect on their structure.

The calculated Pb–Pb separation and C–Pb–C angle in the
dimeric lead structure differ considerably from the
experimentally measured values. The experimental Pb–Pb
distance of 4.129(1) Å in the crystal structure of the
[Pb{CH(SiMe3)2}2]2 dimer25 is far longer than the sum of single
bond covalent radii of 2.88 Å expected for a Pb–Pb single bond.44

Furthermore, the calculated Pb–Pb distances using the B3PW91-
D3 method is 3.241 Å and, by the B97-D3 method, it is 3.256 Å.
These distances are over 1 Å shorter than the experimentally
measured value, and suggest a very weak interaction between the
lead atoms of the Pb{CH(SiMe3)2}2 units in the crystal structure.

Nevertheless, long interactions of this type between the heavier
main group elements can be significant.23 In spite of the
observed deviation in Pb–Pb separation, the experimental and
calculated C–Pb–C angles of the lead dimer are in good agree-
ment with each other. If it is assumed that the Pb{CH(SiMe3)2}2
units within the lead dimer are syn, syn monomers, that is to say
the long Pb–Pb interaction is ignored, the structural parameters
given for Pb{CH(SiMe3)2}2 in Table 1 are obtained. It can be seen
that the calculated C–Pb–C angles of 96.6° (B3PW91), 92.2°
(B3PW91-D3), or 92.0° (B97-D3) are also close to the experi-
mentally-measured value of 93.4(2)°. Moreover, this angle also
resembles those calculated (range 98.4°–94.2°) for the C–Sn–C
angle in the Sn{CH(SiMe3)2}2 monomer (cf. C–Sn–C = 97(2)° by
GED). In effect, the data suggest that the Pb{CH(SiMe3)2}2 units
within the lead dimer are behaving essentially as weakly inter-
acting plumbylene monomers, rather than as a Pb–Pb multiple
bonded diplumbene.

It was noted above that the experimentally-determined
orientation of the –CH(SiMe3)2 groups of the E{CH(SiMe3)2}2
units within the germanium and tin dimers are syn, anti and the
computational data in Table 2 and 3 have been made on the
basis of this orientation. However, it is possible to perform
similar computations with the assumption of syn, syn orienta-
tion in the E{CH(SiMe3)2}2 units. The results of these calcula-
tions are given in Tables S2 and S3.† The changed orientation
results in longer E–E distances and smaller binding energies
of 18.9 (Ge) and 20.0 (Sn) kcal mol⁻¹ at the B3PW91-D3 level
with BSSE and ZPE corrections, which can be compared to the values
of 28.7 (Ge) and 26.3 (Sn) kcal mol⁻¹ in Table 3. In effect, the
changed orientation of the substituents results in binding
energies that are ca. 10 kcal mol⁻¹ lower than the syn, anti
configuration values. These energy differences are somewhat
smaller than the 16.4 kcal mol⁻¹ calculated for the corre-
spanding changes in the energy of the [P(CH(SiMe3)2)2]2 →
2[P(CH(SiMe3)2)2] process upon relaxation of the configurations
from syn, anti to syn, syn.26 The difference in values can be
rationalized, at least in part, in terms of the reduced inter
E{CH(SiMe3)2}2 unit steric crowding because of the larger sizes
of germanium and tin in comparison to that of phosphorus.

It is also informative to consider the effect of altering the
orientation of the CH(SiMe3)2 groups of the Pb(CH(SiMe3)2)2
dimer to the syn, anti orientation observed for the lighter
congeners; the data in Table S4† reflect calculations in this
orientation. The resultant Pb–Pb distance is consistently
shorter than in both the experimental and computational
results in the syn, syn orientation; the dispersion corrected
distance of 2.956 Å (B3PW91-D3) approaches the sum of the
covalent radii indicating a significant degree of Pb–Pb bonding.

<sup>a</sup> Ref. 9. <sup>b</sup> Ref. 10. <sup>c</sup> Ref. 11.
Also noteworthy is the effect upon the C–Pb–C angle which is calculated to widen significantly [91.3 versus 106.6° at the B3PW91-D3 level]; likely a consequence of steric clash between the SiMe\(_3\) groups of the ligand. Such an angle, however, would also optimize Pb–Pb bonding by increasing the p-character of the Pb lone pair. That the Pb(CH(SiMe\(_3\))\(_2\))\(_2\) dimer does not adopt such a conformation must suggest the nature of the Pb(CH(SiMe\(_3\))\(_2\))\(_2\) dimer is that of two weakly interacting plumbylene monomers wherein significant s-character of the lone pair enforced by the narrow C–Pb–C angles (93.4(2)°) lead to “closed-shell” interactions between the Pb atoms.

**Calculated thermodynamic data for the dissociation of the [E(CH(SiMe\(_3\))\(_2\)]\(_2\), dimers**

The data for the dissociation of the dimeric [E(CH(SiMe\(_3\))\(_2\)]\(_2\), to two E(CH(SiMe\(_3\))\(_2\)) monomers are summarized in Table 3. Without inclusion of dispersion effects, it can be seen that the binding energies are −2.3, 2.1, and 0.6 kcal mol\(^{-1}\) for the germanium, tin, and lead dimers without dispersion force correction, and +9.4, +7.1, and −1.7 kcal mol\(^{-1}\). These negative values are consistent with the monomeric equilibrium of the E\(_2\)R\(_4\) (E = Ge, Sn, or Pb; R = CH(SiMe\(_3\))\(_2\)) series.

This was accomplished by variable-temperature NMR spectroscopy of [Sn(CH(SiMe\(_3\))\(_2\)]\(_2\), and the behavior of the \(^{13}\)C shifts of the methine carbons in the monomers and dimers. This allowed calculation of \(\Delta H = 12.8\) kcal mol\(^{-1}\) and \(\Delta S = 33\) cal K\(^{-1}\) mol\(^{-1}\) for the dissociation. These experimental values differ considerably from those calculated (cf. \(\Delta H = 27.0\) kcal mol\(^{-1}\) and \(\Delta S = 66.7\) cal K\(^{-1}\) mol\(^{-1}\)). At present, the reason for the discrepancy between the experimental and calculated values is unclear, and more data will be required to establish the expected values for similarly-substituted monomer–dimer equilibria. For example, significantly higher \(\Delta S\) values of 75 and 66 cal mol\(^{-1}\) K\(^{-1}\) have been determined for the dissociation of the [M\(_n\)N(SiMe\(_3\))\(_2\)]\(_2\), (M = Fe or Co), which carry \(-N(SiMe\(_3\))\(_2\) substituents that are isoelectronic to CH(SiMe\(_3\))\(_2\).

The dissociation of the digermene [Ge(C\(_6\)H\(_2\)-2,4,6-Me\(_3\)){C\(_6\)H\(_2\)-2,4,6-(CH(SiMe\(_3\))\(_2\))\(_3\})\(_2\)] was studied by electronic spectroscopy which revealed a \(\Delta H\) value of 14.7(2) kcal mol\(^{-1}\) and a \(\Delta S\) value of 42.4 cal mol\(^{-1}\) K\(^{-1}\).

A rationalization for the observed congeneric variation can thus be constructed wherein the interplay between the effects of

### Table 3  Thermodynamic data (kcal mol\(^{-1}\)) for the dissociation of the dimetaallenes [E(CH(SiMe\(_3\))\(_2\)]\(_2\), into two metallanediyl syn, syn monomers, E(CH(SiMe\(_3\))\(_2\))\(_2\)

\(\Delta E\) Dissociation energy (kcal mol\(^{-1}\)), MP2 values are in parentheses. \(\Delta F\) With ZPE and BSSE corrections. \(\Delta H\) at 25 °C (298 K) and 1 atm. \(\Delta S\) at 155 °C (429 K) and 0.1 Torr. \(\Delta G\) at 120 °C (393 K) and 0.1 Torr.
dispersion interactions, steric congestion and metal–metal bond strength define the observed structures of the \([\text{E} \{\text{CH(SiMe}_3\text{)}_2\}_2\] \(\text{E} = \text{Ge, Sn, Pb}\) dimers. The syn, anti conformation adopted by germanium and tin yields an increased interligand steric congestion,\(^4\) and thus other factors must stabilize the adoption of this orientation in the dimers. In contrast, such stabilization must be insufficient in the case of the lead congener which results in the adoption of a less crowded syn, syn orientation and consequent attenuation of metal–metal bonding. This conclusion is supported by the fact that the seven-membered ring dialkyl lead(II) species \(\text{Pb} \{\text{SiMe}_3\}_2 \text{Cl}_2 \text{SiMe}_2 \text{CH}_2 \text{SiMe}_2 \text{Cl}(\text{SiMe}_3)_2\) has a very similar substitution pattern to that in \([\text{Pb} \{\text{CH(SiMe}_3\text{)}_2\}_2\] \(\text{E} = \text{Ge, Sn, Pb}\) dimers and a C-Pb-C angle of \(117.1(2)\)°, has no Pb-Pb contact shorter than \(8.911\) Å. Furthermore, the Sn(II) dialkyl \(\text{Sn} \{\text{SiMe}_3\}_2 \text{Cl}_2 \text{Cl}(\text{SiMe}_3)_2\),\(^5\) featuring the tin atom in a five-membered ring structure and a C-Sn–C angle of \(86.7(2)\)°, is also monomeric. Here the C(SiMe\(_3\))\(_2\) moieties have a syn, syn-like conformation analogous to the vapor phase structure of Sn(II) dimers and the lead congener in all cases. These data suggest that a syn, syn orientation precludes strong M–M contact and thus any dimerisation must emerge principally from dispersion interactions.

In the case of the germanium and tin congeners, two factors clearly stabilize the sterically unfavorable adoption of a syn, anti orientation; the strength of dispersion forces and the degree of metal–metal bonding. The dispersion interactions in these dimers is evidently optimized between different ER\(_2\) fragments favoring dimerisation, as evidenced by the increase in C–E–C angle when dispersion corrected (Ge = \(109.9\)° (B3PW91), \(111.8\)° (B3PW91-D3); Sn = \(109.8\)° (B3PW91), \(111.2\)° (B3PW91-D3)). These data reinforce that dispersion effects are the principal driving force for dimerisation in these species and act as a scaffold for metal–metal bonding.

In contrast, the application of a dispersion correction to the lead structure yields, in the case of the experimentally consistent syn, syn orientation a contraction of the C–M–C angle (96.8° (B3PW91), \(91.3\)° (B3PW91-D3)) or in the case of the putative syn, anti orientation a negligible change (106.3° (B3PW91), 106.6° (B3PW91-D3)). These data are a likely consequence of the increase in E–C bond length down group 14, precluding dimer-favoring dispersion interactions in the Pb case, and instead favoring intramonomer interactions which cannot stabilize the steric clash introduced by a syn, anti orientation of the ligands. Furthermore, this narrowing of the C-Pb–C angle increases the s-character of the Pb centered lone pair, disfavoring metal–metal bonding further indicating that any Pb–Pb interactions are closed-shell in nature.

### The amido monomers \([\text{E} \{\text{SiMe}_3\}_2\] \(\text{E} = \text{Ge, Sn, or Pb}\)

The calculated and experimental structural parameters for the three monomeric amido derivatives \([\text{E} \{\text{SiMe}_3\}_2\] \(\text{E} = \text{Ge, Sn, or Pb}\) are provided in Table 4. Diffraction data for both the gas (GED) and crystalline phases (X-ray), which show that each has a monomeric structure, are listed. The experimental data for the gas and crystalline phases differ considerably in their N–E–N angles and the dihedral angles between the EN\(_2\) and NSi\(_2\) coordination planes. It can also be seen that the N–E–N angle is much more sensitive to the identity of the central atom (E) in the vapor phase than in the solid state. Furthermore, the N–E–N angle is significantly narrower for the tin and lead compounds in the vapor phase than in the solid state. Such differences have been attributed to the changed ligand orientation in the gas phase, where the NSi\(_2\) planes are essentially perpendicular to the EN\(_2\) plane.\(^5\) This may minimize steric repulsion because of the parallel orientation of the NSi\(_2\) planes. However, it would give inefficient packing in the solid state. As a result, the –NSi\(_2\) ligand planes are tilted with respect to the EN\(_2\) plane in the crystal structure. In addition, they have close intramolecular contacts as well as different E–N–Si angles for the ‘inner’ (wider E–N–Si angle) and ‘outer’ (narrower E–N–Si angle) SiMe\(_3\) groups. The differences are ca. \(12.3\)° for the Ge, ca. \(11\)° for the Sn, and ca. \(8.5\)° for the lead species. Inspection of the theoretical data show that there is good agreement with the calculated bond lengths for both the vapor and crystal phase structures. However, for the key N–E–N and E–N–Si angles, there is good agreement only in the case of the X-ray crystallographic data, where the calculated bond lengths, N–E–N angles, and the different ‘inner’ and ‘outer’ E–N–Si angles are faithfully reproduced in the calculations. The X-ray data show that the shortest E–E distances in the three crystal structures are \(5.36\) Å (Ge), \(4.96\) Å (Sn), and \(6.66\) Å (Pb). In the tin structure, the relative orientation of the tins is head to head between the closest monomers, and although there is a \(0°\) torsion angle between the peripherals to the SmN\(_2\) planes, there is a displacement of the units with respect to each other such that imaginary lines bisecting the SmN\(_2\) angles are parallel to each other but are \(0.52\) Å apart.

### Structural and thermodynamic data for the putative amido dimers \([\text{E} \{\text{SiMe}_3\}_2\] \(\text{E} = \text{Ge, Sn, or Pb}\)

The calculated structural parameters and dissociation energies of the putative \([\text{E} \{\text{SiMe}_3\}_2\] \(\text{E} = \text{Ge, Sn, or Pb}\) dimers at various levels of optimization are given in Table 5. The calculated structural parameters for the \([\text{E} \{\text{SiMe}_3\}_2\] \(\text{E} = \text{Ge, Sn, or Pb}\) units within the dimers are close to those calculated for the monomeric structures which match those experimentally determined by X-ray crystallography. The E–E distances undergo large contractions when dispersion force corrections are included. However, the shortest distances calculated for the germanium and tin amido dimers, even with the inclusion of such forces at the B3PW91-D3 level, are significantly longer (by ca. \(1.4\) and \(0.7\) Å) than the measured values and the values calculated at the same level for the alkyl dimers. The metal–metal distance calculated for the amido-ligated lead dimer (3.714 Å) by the B3PW91-D3 method is ca. \(0.5\) Å longer than the corresponding calculated distance (3.241 Å) in the dialkyl lead dimer. These distances indicate considerably weaker interactions between the group 14 elements for the amido derivatives. Thermodynamic data (Table 5) for the amido dimers also provide further evidence for weak association. The binding energies calculated without the inclusion of dispersion forces for the germanium, tin, and lead amido dimers at the B3PW91 level yield negative values of \(−5.0\),

$^a$ Ref. 7. $^b$ Ref. 4 and 5. $^c$ Ref. 5.

$–3.5$, and $–4.1$ kcal mol$^{-1}$, respectively, and show that the E–E interaction is disfavored (cf. positive values of 5.6, 12.0, and 0.1 for the alkyls, Table 1). In other words, monomeric structures are favored in each case. However, at the B3PW91-D3 level, which includes dispersion force effects, the energies change to 8.4, 19.8, and 15.6 kcal mol$^{-1}$. Using the B97-D3 method affords similar but somewhat lower values of 7.9, 16.4, and 12.5 kcal mol$^{-1}$. Single point MP2 calculations yield corresponding values of 5.1, 15.6, and 3.9 kcal mol$^{-1}$. The overall picture that emerges from the calculations on the amides is that the dimerization tendency is present but weaker than it is in the alkyls, and that the driving force for the association of the monomers is due to dispersive attraction forces the $–N$(SiMe$_3$)$_2$ ligands. Further calculations on the thermodynamics of dissociation show that the $\Delta G$ energies for the process are $–16.4$, $–18.0$, and $–10.8$ kcal mol$^{-1}$ at 25 °C and 1 atm, so that dissociation and monomeric structures are favored under these conditions. These findings are, of course, consistent with the structural and physical data. The much weaker E–E interactions in the amides in comparison with the alkyls is probably a result of electronic and steric factors. The more electronegative $–N$(SiMe$_3$)$_2$ ligand causes a larger HOMO–LUMO separation on the E atom, which would lower the extent of orbital interaction between the monomers. Also, the configurational differences between the $–CH$(SiMe$_3$)$_2$ and $–N$(SiMe$_3$)$_2$ (no syn, syn–syn, anti configurational change is possible for the amido ligands) may lead to greater steric hindrance, and hinder the association of the two monomeric fragments in the case of the amido ligand.

**Persistent dimers of stannylenes: the case of [Sn[SiMe$_3$Bu$_2$$_2$]]$_2$**

With these analyses in hand, it is informative to consider other stannylenes in the literature. Whilst a plethora of such species have been reported, the vast majority are monomeric in solution, and many with extremely sterically demanding ligands remain monomeric in the solid state. One notable exception is [Sn[SiMe$_3$Bu$_2$$_2$]]$_2$, described by Sekiguchi, Apeloig and co-workers in 2006. This species persists as a dimer in solution and, in contrast to the vast majority of literature examples, reverts as a dimer. It has a very short Sn–Sn distance of 2.6683(10) Å and essentially planar coordinated tin atoms, but the tin coordination planes subtend an angle of 44.62(7)° with respect to each other. This led the authors to propose that the Sn–Sn bonding was a result of a triplet–triplet interaction between the two stannylenes on the basis of calculations on the model species Sn$_2$(SiMe$_3$)$_4$. While no full molecule calculations have been reported for [Sn[SiMe$_3$Bu$_2$$_2$]]$_2$ to investigate dispersion force contributions, a qualitative assessment can be made. One notable feature of dispersion force interactions is their dependence on length-scale and they are thought to be highly attenuated beyond the sum of the van der Waals radii of the interacting atoms. Thus, a qualitative assessment of
dispersion forces can be undertaken by analysing for sub-van der Waals distances in structures.

As shown, analysis of the crystallographically defined structures of [Sn(CH(SiMe3)2)2]2 and [Sn(SiMe3)2]2 indicates that such a sterically unfavourable conformation is partly stabilised by dispersion interactions.

In the case of [Sn(SiMe3)2]2, several dispersion interactions are evident between each of the interacting Sn(SiMe3)2 fragments, and they occur with greater frequency than in the [Sn(CH(SiMe3)2)2]2 species. Whilst the report of [Sn(SiMe3)2]2 provides an extensive electronic rationale for Sn–Sn interactions being responsible for its observed dimeric structure and short Sn–Sn distance, it is likely that dispersion forces are also of importance in stabilising the persistent dimeric nature of this compound.

To check this hypothesis, our initial full molecule calculations (see Table S5† on [Sn(SiMe3)2]2 confirm the presence of a shorter tin–tin bond (2.647 Å) than that in [Sn(CH(SiMe3)2)2]2. However, the calculations show that the binding energy increases from 25.8 to 46.8 kcal mol\(^{-1}\) with inclusion of dispersion effects, and that the \(\Delta G\) of dissociation at 25 °C and 1 atm is increased from 8.3 to a value of 26.5 kcal mol\(^{-1}\) upon inclusion of the dispersion correction, indicating that the dispersion force attraction is of key importance in maintaining the dimeric structure.

Conclusions

The calculations have shown that the interplay between dispersion force attraction, steric repulsion and element–element bonding stabilize the dimeric structures. Although the E=E distances indicate E=E bonding is present in the germanium and tin dimers, and possibly the lead dimer, the bonding is weak, and represents a relatively small fraction of the binding energy. The results emphasize the importance of including attractive dispersion force interactions in consideration of multiple bonded heavier main group element species where sterically encumbering ligands are employed in their stabilization. Furthermore, these effects act in harmony with a variety of other stabilizing and destabilizing effects (e.g. packing or conformational) which are notable particularly for the –CH(SiMe3)2 ligand. A similar analysis for the non-dissociating distannene [Sn(SiMe3)2]2 shows that in this molecule also, the dispersion forces are of key importance in its stabilization. These studies provide an initial framework for the analysis of metal–metal bonding which takes into account these more subtle effects. Although much effort has been expended in development of bonding models for the multiple bonds between heavier main group elements, it seems both probable and ironic that the dispersion force attraction forces exceed those of the multiple bonds in many instances and that a variety of more subtle interactions including packing effects are of key importance for the understanding of their bonding.
