ABSTRACT

Aim: This study investigated the value of regional cerebral oxygen saturation (rSO2) monitoring upon arrival at the hospital for predicting post-cardiac arrest intervention outcomes.

Methods: We enrolled 1195 patients with out-of-hospital cardiac arrest of presumed cardiac cause from the Japan-Prediction of Neurological Outcomes in Patients Post-Cardiac Arrest Registry. The primary endpoint was a good neurologic outcome (cerebral performance categories 1 or 2 [CPC1/2]) 90 days post-event.

Results: A total of 68 patients (6%) had good neurologic outcomes. We found a mean rSO2 of 21% ± 13%. A receiver operating characteristic curve analysis indicated an optimal rSO2 cut-off of ≥40% for good

Introduction

The advent of systematic bundled post-cardiac arrest interventions (PCAI) has increased the likelihood of patients surviving with good neurologic function after out-of-hospital cardiac arrests (OHCA). In particular, therapeutic hypothermia (TH) and percutaneous coronary intervention (PCI) with emergent coronary angiography (CAG) have been reported to improve the prognoses of patients following OHCA of presumed cardiac cause.

On the other hand, recent studies have shown that TH does not provide a beneficial effect following OHCA. In fact, brain damage severity estimations and outcome prognoses for OHCA patients were found to be inaccurate, implying that stratification before or imbalance corrections after randomisation might have been problematic in many previous studies. Additionally, the absence of appropriate measurements for brain damage severity estimations and prognosis determinations might make it difficult to perform stratified randomisations in clinical trials involving patients experiencing OHCA of presumed cardiac cause. Thus, better prognostic factors are needed to elucidate ‘true indications’ of PCI outcomes following such events.

Regional cerebral oxygen saturation ($rSO_2$) is a measure of cerebral perfusion that is obtained noninvasively via near-infrared spectroscopy and monitored in patients during cardiac arrest since the instrument does not require vascular pulsation. We previously reported that $rSO_2$, measured upon arrival at the hospital, might help predict neurologic outcomes in patients following OHCA. However, few studies have focused on whether $rSO_2$ measurements are effective for estimating brain damage severity, for determining prognoses, or in the decision-making process for PCI in patients who have experienced OHCA of presumed cardiac cause. Therefore, this study aimed to evaluate the clinical usefulness of $rSO_2$ monitoring to estimate the severity of brain damage and determine the prognoses of patients following OHCA of presumed cardiac causes.

Methods

Study design and setting

The Japan-Prediction of Neurological Outcomes in Patients Post-cardiac Arrest (J-POP) Registry is a prospective multicentre cohort study, and 15 Japanese tertiary emergency care hospitals participated in the J-POP during the study period (15 May 2011 to 30 August 2013). The inclusion criterion was unresponsiveness during and after resuscitation upon arrival at the hospital following an OHCA. The exclusion criteria included (1) trauma, (2) accidental hypothermia, (3) age <18 years, (4) completion of the ‘Do Not Attempt Resuscitation’ form, and (5) a Glasgow coma scale (GCS) score >8 upon arrival at the hospital. The details of the J-POP registry design and main outcomes have been published elsewhere.

To identify the value of emergency room $rSO_2$ measurements in the PCI (including TH and CAG) decision-making process, we analysed 1195 consecutive patients with OHCA of presumed cardiac cause from the J-POP registry.

Emergency medical care in Japan

In Japan, emergency lifesaving technicians are permitted to insert tracheal tubes and administer intravenous adrenaline (epinephrine). All emergency medical service providers perform cardiopulmonary resuscitation (CPR) according to the current CPR guidelines. However, the providers are not permitted to terminate CPR in the field.

Procedures after arrival at the hospital

All patients received advanced life support in accordance with national guidelines. If sustained return of spontaneous circulation (ROSC), i.e., the restoration of a palpable pulse that is sustained for at least 20 min, was not obtained using standard advanced life support, patients with initially documented ventricular fibrillation or pulseless ventricular tachycardia received extracorporeal CPR and extracorporeal circulatory support or a cardiopulmonary bypass. If patients obtained sustained ROSC, TH was induced once their systolic blood pressure exceeded 90 mmHg and their GCS score was 3–8. All procedural (e.g., extracorporeal CPR, CAG, PCI, and TH) and diagnostic decisions were made at the discretion of the attending physician(s).

Data collection

Data were prospectively collected according to the Utstein style. Baseline patient characteristics and in-hospital data were collected from medical records and databases.

Cardiac arrest was defined as the absence of spontaneous respiration, a palpable pulse, and stimuli responsiveness. The arrest was presumed to be of cardiac origin unless it was due to cerebrovascular disease, respiratory disease, external factors (e.g., drug overdose or asphyxia), or other non-cardiac factors.

Near-infrared spectroscopy

Upon arrival at the hospital, 2 disposable near-infrared spectrometers (INVOS™ 5100C; Covidien, Boulder, CO, USA) probes were carefully applied to both sides of the patient’s forehead. After several seconds of stabilisation, $rSO_2$ was monitored using the probes for at least 1 min, and the lowest $rSO_2$ reading was recorded.

Fig. 1. Study flow. CPC, Glasgow–Pittsburgh cerebral performance category; GCS, Glasgow Coma Scale; OHCA, out-of-hospital cardiac arrest; rSO2, regional cerebral oxygen saturation.

Study endpoints

The primary endpoint was the patients’ 90-day neurologic outcomes, categorised according to the Glasgow–Pittsburgh cerebral performance categories (CPC), described in the Utstein style guidelines. The guidelines categorise CPC 1 (good performance) and CPC 2 (moderate disability) as ‘good neurologic outcomes’, whereas CPC 3 (severe disability), CPC 4 (vegetative state), and CPC 5 (brain death or death) are defined as ‘poor neurologic outcomes’. Individual patient CPC were determined by at least 2 physicians-in-charge who were blinded to the rSO2 readings determined upon arrival at the hospital.

Statistical analyses

Unpaired \( t \)-tests or Mann–Whitney \( U \)-tests were conducted for unpaired comparisons. A \( \chi^2 \) or Fischer’s exact test was conducted to examine differences between categorical variables. Receiver operating characteristic curve (ROC) analysis was performed to evaluate the accuracy of predicted post-event good neurologic outcomes at 90 days. To analyse the effects of rSO2 on neurologic outcomes, we developed logistic regression models that were adjusted for a pulse detectable upon arrival at the hospital, defibrillation before arrival at the hospital, bystander-initiated CPR, age, male sex, use of an advanced airway device before arrival at the hospital, and intravenous epinephrine administration before arrival at the hospital, in addition to rSO2 upon arrival at the hospital. The JMP (version 10.0.0, SAS Institute, Cary, NC, USA) and STATA (version 11.1, Stata, College Station, TX, USA) software were used for all statistical analyses. All reported probability values are 2-tailed, and \( P < 0.05 \) was considered statistically significant.

Ethical considerations

This study complied with the Declaration of Helsinki and conformed to the Guidelines for Epidemiologic Studies issued by the Ministry of Health, Labour, and Welfare of Japan. The study protocol was approved by the institutional review board or ethics committee of each participating medical institution, which also waived the requirement for informed consent.

Results

General patient characteristics and outcomes

During the study period, the registry accumulated data on 3086 consecutive OHCA patients who were referred to the 15 participating hospitals. In accordance with the study protocol, 1921 consecutive patients were enrolled, and 1195 patients with OHCA of presumed cardiac cause were included in the analysis (Fig. 1).

Table 1 shows the characteristics and neurologic outcomes of all patients. Among all patients, 880 (74%) were pronounced dead in the emergency department. Of the remaining 315 patients, 223 (19%) died after admission to the hospital, whereas 92 (8%) survived for at least 90 days. After 90 days, 55 (5%), 13 (1%), 6 (0.5%), and 18 (2%) patients were classified as CPC 1, 2, 3, and 4, respectively. Accordingly, 68 patients (6%) were considered to have good neurologic outcomes (CPC 1 or 2).

Fig. 2. Receiver operating characteristic curve analysis of regional cerebral oxygen saturation upon arrival at the hospital as a predictor of good 90-day neurologic outcomes and neurologic outcomes according to regional cerebral oxygen saturation cut-off values. AUC, area under the curve; CI, confidence interval; CPC, Glasgow–Pittsburgh cerebral performance category; ROC, receiver operating characteristic; ROSC, return of spontaneous circulation; rSO2, regional cerebral oxygen saturation.
are shown in Table 1. Good neurologic outcomes were observed for
53% (55/103) and 1% (13/1092) of the patients with rSO2 ≥40% and
<40%, respectively (P < 0.001, Fig. 2).

Of the 89 comatose patients whose pulse could be detected upon
arrival at the hospital, 73 had rSO2 ≥40% and 16 had rSO2 <40%
(Fig. 3). Among these patients, 46 (63%) patients with high rSO2
measures had good neurologic outcomes. None of these patients
had low rSO2 (P < 0.001). Of the 1106 patients whose pulse could
not be detected upon arrival at the hospital, 30 had rSO2 ≥40% and
1076 had rSO2 <40% (Fig. 3). Among these patients, good neuro-
logic outcomes were observed for 9 (30%) patients with high rSO2
measures and 13 (1%) with low rSO2 (P < 0.001).

Multivariate analyses for good neurologic outcomes

Multivariate analyses (adjusted for prehospital patient char-
acteristics that showed a significant univariate association with
outcomes) for good neurologic outcomes associated with prehos-
ital variables and high (≥40%) rSO2 indicated that high rSO2 was
independently associated with good neurologic outcomes (odds
ratio 14.07, 95% CI 5.01–39.86, P < 0.001; AUC 0.96; Table 2).

Post-cardiac arrest interventions

Extracorporeal CPR, TH, CAG, and PCI were performed in 95 (8%),
154 (13%), 135 (11%), and 64 (5%) patients, respectively.
A higher proportion of patients who underwent TH had good
neurologic outcomes (CPC1/2; 36%) than those not undergoing TH
(CPC1/2; 1%, P < 0.001). Similarly, a higher proportion of patients
who underwent a CAG had good neurologic outcomes (CPC1/2;
41%) than those who did not (CPC1/2; 1%, P < 0.001). Last, patients
who underwent TH or a CAG showed significantly more favourable
characteristics (Table 1).

Furthermore, more than two thirds of patients with rSO2 ≥40%
who underwent TH or a CAG showed good neurologic outcomes
(CPC1/2; 69%; Fig. 3), and this rate of good neurologic outcomes
rate was significantly higher than in patients with rSO2 <40%
who underwent the same procedures (CPC1/2; 11%; P < 0.001).
However, among patients with rSO2 ≥40%, 24% (25/103) did not
undergo TH or a CAG. These patients exhibited a significantly lower
rate of good neurologic outcomes than those undergoing TH or a
CAG (CPC1/2; 4% vs. 69%, respectively; P < 0.001; Fig. 3). Many of
these patients had other unfavourable characteristics such as older
age, OHCA at home, no witnesses, no bystander-initiated CPR, no

shockable rhythms, and no detectable pulse upon arrival at the hospital (Table 3).

Discussion

Our results show that high rSO2 upon arrival at the hospital predicted good 90-day neurologic outcomes with high sensitivity, specificity, and AUC (optimal cut-off, rSO2 ≥40%) in patients experiencing OHCA of presumed cardiac cause. These data are consistent with our previous report on all non-trauma OHCA patients in the J-POP Registry.12 Half of the patients (55/108, 51%) with rSO2 ≥40% upon arrival at the hospital had good neurologic outcomes. Surprisingly, even if a pulse was not detectable upon arrival at the hospital, 30% of patients (9/30) with high rSO2 demonstrated good neurologic outcomes. In contrast, none of the patients (0/19) with low rSO2 had good neurologic outcomes, even if a pulse was detected upon arrival at the hospital. These compelling results show that rSO2 monitoring is a promising method for selecting good candidates for PCAI (including TH, CAG, and PCI). To the best of our knowledge, this is the first report demonstrating the clinical usefulness of rSO2 measurements for estimating brain damage severity and predicting outcomes in patients with OHCA of presumed cardiac origin.

As reported by Ito et al. 2/446 (0.4%) patients demonstrated good 90-day neurologic outcomes despite having low rSO2 (15%) upon arrival at the hospital, implying that rSO2 values alone cannot be used to determine whether resuscitative efforts should be terminated. Therefore, rSO2 monitoring is useful for determining which patients will likely have good neurologic outcomes following OHCA of presumed cardiac cause (i.e. which patients are good PCAI candidates).12

Many studies have shown strong positive effects of bundled PCAI for improving post-cardiac arrest outcomes.12,22 Another multicentre registry study in Japan reported that 55% of OHCA patients had good neurologic prognoses after PCAI.23 In the present study, up to 69% of patients with rSO2 ≥40% showed good neurologic prognoses if they underwent PCAI. Thus, monitoring rSO2 in the emergency room, following OHCA of presumed cardiac cause, provides a good indication of the 90-day neurologic outcomes following PCAI. However, in the present study, approximately 25% patients with high rSO2 did not undergo TH or a CAG and these patients exhibited a significantly lower rate of good neurologic outcomes than those undergoing TH or a CAG (CPC1/2; 4% vs. 69%, respectively: P < 0.001; Fig. 3). High rSO2 values upon hospital arrival indicated that the patients did not suffer from severe hypoxic cerebral damage. Thus, we hypothesised that rSO2 was an intermediate factor in the process of cerebral damage formation after OHCA, and that high rSO2 values upon hospital arrival indicated that the patients might be good candidates for PCAI even if they had unfavourable characteristics. In fact, unfavourable characteristics were relatively common among these patients, PCAI might have been underutilised in these individuals. Further studies are needed to determine whether patients in this group are good candidates for PCAI.

TH at a target temperature of 33 °C was recently reported not to confer a benefit over TH at a target temperature of 36 °C, implying the overuse of PCAI. Rittenberger et al.24 remarked that future studies should continue to define patient subgroups that would benefit from specific therapies and clarify protocols for such interventions, based on each patient’s illness, including a mandatory estimation of brain damage severity. Further studies are needed to clarify whether rSO2 monitoring in the emergency room is useful for
predicting brain damage severity and making decisions regarding PCIA administration.

This study has several limitations. Although we previously reported that continuous rSO2 monitoring would be desirable prior to arrival at the hospital, the absence of portable near-infrared spectroscopy devices makes this impossible.12 Second, near-infrared spectroscopy rSO2 measurements reflect only cerebral perfusion in the superficial layers of limited frontal lobe areas, and rSO2 is not a reliable marker of brain tissue oxygen partial pressure.10–12 Third, we could not blind the investigators to the rSO2 values because rSO2 monitoring requires real-time visual confirmation. As per a pre-specified protocol, all patients received the best available therapy, regardless of their rSO2;12 however, we could not eliminate the possibility that low rSO2 might have influenced the decision to terminate resuscitation. Fourth, as emergency medical service providers in Japan are not permitted to terminate CPR, most OHCA patients who are treated by these personnel are transported to emergency departments. Thus, a very small proportion of patients with documented rhythms at the scene of cardiac arrest demonstrated ventricular tachycardia/fibrillation and had very poor 90-day neurologic outcomes. Hence, the international validity of this study might be limited. Finally, this study was not randomised, and to assess the predictive value of a clinical tool, precise validation cohorts are needed to verify our observations.

Conclusions

In conclusion, our study shows that rSO2 >40% upon arrival at the hospital predicted good 90-day neurologic outcomes in patients suffering OHCA of presumed cardiac cause, even if a pulse was undetectable upon arrival at the hospital. Patients with rSO2 >40% upon arrival at the hospital who underwent PCIA showed remarkably favorable neurologic prognoses. Thus, rSO2 monitoring following OHCA of presumed cardiac cause is an indicator of 90-day neurologic outcomes following PCIA. However, about 25% of patients with rSO2 >40% in our study did not undergo TH or a CAG and had quite poor neurologic outcomes, implying that PCIA might be underutilised in these cases. Future studies are necessary to evaluate the efficiency of rSO2 monitoring during the PCIA decision-making process following OHCA of presumed cardiac cause.

Conflict of interest statement

Dr. Nishiyama conducted an investigator-sponsored study (Covidien, Japan) entitled ‘Pre-hospital Resuscitation for Sustaining Cerebral Oxidation: Observational Cohort Study’ The other authors declare no conflicts of interest.
