(Received 16 April 2015; revised manuscript received 28 May 2015; published 29 July 2015)

We report quantum oscillation data on the metallic triangular antiferromagnet PdCrO₂. We find that, to very high accuracy, the observed frequencies of PdCrO₂ can be reproduced by reconstruction of the (nonmagnetic) PdCoO₂ Fermi surface into a reduced zone. The reduced zone corresponds to a magnetic cell containing six chromium sites, giving a √3 × √3 in-plane reconstruction, and √2 interplane reconstruction. The interplane ordering represents a reduction in lattice symmetry, possibly to monoclinic, and an associated lattice distortion is expected. In addition, we report a magnetic transition under an applied in-plane field that is probably equivalent to the spin-flop transition reported for CuCrO₂, and present data on its field-angle dependence. We also report measurements of the resistivity of PdCrO₂ up to 500 K.

DOI: 10.1103/PhysRevB.92.014425 PACS number(s): 71.10.Fd, 75.30.Kz, 75.50.Ee

Magnetic ions coordinated on a triangular lattice often yield interesting magnetic properties. A prominent example is the insulating CrO₂ sheet, stabilized in materials such as LiCrO₂ and PdCrO₂. In these compounds, the Cr formal charge is +3, and its configuration is 3d⁵. The crystal field at the Cr sites is nearly octahedral, inducing a gap between the quasi-3t₂g (dₓ²−ᵧ², dₓz, and dᵧz) and quasi-e₉ (d₃z²−r² and dₓ−ᵧ) bands. The e₉ bands lie above the Fermi level, and the 3t₂g bands are half-filled.

CuCrO₂ show spin-driven ferroelectricity, while NaCrO₂ and LiCrO₂ do not [2]. AgCrO₂ and CuCrO₂ have the delafossite structure and NaCrO₂ and LiCrO₂ the ordered rock-salt structure, but the more essential difference appears to be the interlayer ordering: in AgCrO₂ [3] and CuCrO₂ [4,5], the interlayer ordering is ferroic, in that the vector chirality, the rotational sense of the spin helices that comprise the 120° phase, is the same in all layers. In LiCrO₂, in contrast, neutron scattering data suggest that the vector chirality alternates from layer to layer [6], while the interplane ordering of NaCrO₂ is not clear [7].

This paper focuses on PdCrO₂. The Néel temperature of PdCrO₂ is T_N = 37.5 K, and, like LiCrO₂, the vector chirality probably alternates from layer to layer [1,8], so this feature is not restricted to the ordered rock-salt structure.

Whereas the other compounds discussed above are insulators, PdCrO₂ is a metal [9], due to Pd 4d/5s conduction. The isomorphic, nonmagnetic compound PdCoO₂ also has the Pd sheets, and its carrier mobility was found to exceed that of copper [10]. In PdCoO₂, the strongest d contribution appears to be from the 4dₓz, whereas the relative weight of this and Pd 5s at the Fermi level is not clear [11,12]. PdCrO₂, therefore, is an interesting system, comprised of highly conducting sheets interleaved with Mott insulating spacer layers. The resistivity anisotropy (ρₜ/ρₘ) is about 180 at 295 K, and about 290 at 30 K [13]. It would be interesting to determine whether the metallic Pd conduction has any effect on the magnetic order.

What is certainly true is that the Pd conduction can be used as a probe of the magnetic order. Quantum oscillation [14] and angle-resolved photoemission spectroscopy (ARPES) [15,16] studies have shown that the PdCrO₂ Fermi surfaces result from reconstruction of the PdCoO₂ Fermi surface into the magnetic zone. Observation of an unconventional anomalous Hall effect

I. METHODS

Single crystals of PdCrO$_2$ were grown by a NaCl flux method, using PdCrO$_2$ powder synthesized via a solid-state reaction [18]. We measured magnetic oscillations in two samples of PdCrO$_2$, by torque magnetometry, using the same piezoresistive AFM cantilevers as in our previous study on PdCoO$_2$ [10,19]. The cantilevers were mounted on rotatable platforms with integrated field angle sensors. Some raw data for sample #1 are shown in Fig. 1.

Sample #1 was roughly $230 \times 300 \times 11$ $\mu$m, and sample #2 $160 \times 100 \times 15$ $\mu$m. For sample #1, the field was rotated about a (1000) axis (using hexagonal indexing), and for sample #2 a (1100) axis; these axes are illustrated at the bottom right of Fig. 2. Both samples showed strong low-frequency oscillations ($\sim 800$ T for field angle $\theta \to 0$) that dominate the data. In sample #1, at 0.7 K these oscillations were discernible at fields as low as 2 T. At high fields (above $\sim 10$ T), the oscillation amplitude was very large, leading to strong torque interaction: the oscillations had a triangular form, and strong sum and difference frequencies appeared in the Fourier transforms. While torque interaction complicates the analysis somewhat, it may be difficult to avoid if the samples are to be large enough for higher-frequency oscillations to be resolved.

The oscillation amplitudes were history dependent. Cooling the sample through $T_N$ in a 15-T field resulted in oscillation amplitudes for the $\alpha$, $\beta$, and $\gamma$ orbits (illustrated in Fig. 3) roughly four times as large as with zero-field cooling. These large amplitudes persisted as long as the field was maintained. Releasing the field and heating the sample to $\sim 1$ K caused the amplitudes to decrease, and reapplying fields up to 15 T did not recover the large amplitudes. The system therefore appears to be nonergodic. A possible origin of glassy behavior is domain-boundary Cr spins: the relatively large magnetic unit cell of PdCrO$_2$ means that in the absence of training a complex domain structure is likely.

in PdCrO$_2$ indicates further that the Cr spins are not coplanar [17].

In this paper, we present measurements of quantum oscillations in PdCrO$_2$, and confirm the overall frequencies reported in Ref. [14]. We add greater resolution and a careful comparison with the nonmagnetic PdCoO$_2$ Fermi surface: we show that reconstruction of the PdCoO$_2$ Fermi surface reproduces most of the observed oscillation frequencies to very high accuracy: the PdCrO$_2$ frequencies can be analyzed in detail without recourse to density functional theory calculations.

We also report a magnetic transition under applied field, at a similar field to a spin-flop transition reported in CuCrO$_2$, that was observed in the course of measurement of the oscillations. Finally, we present measurements of the resistivity of PdCrO$_2$ to high temperatures.

FIG. 1. Magnetic oscillations in sample #1 at three field angles. The $y$ scale is the resistance of the piezoresistive sense element on the cantilever.

FIG. 2. The observed oscillation frequencies of PdCrO$_2$, multiplied by $\cos(\theta)$, against field angle $\theta$. The field rotation axes are shown at bottom right, referenced to the nonmagnetic zone. The frequencies are from Fourier transformation of the data over the range 4.2 to 15 T. Frequencies that are clearly sum or difference frequencies are not shown. The indicated amplitudes of the oscillations are peak-to-peak amplitudes of the resistance of the sense element on the cantilever. The PdCoO$_2$ frequencies are taken from the model in Ref. [10], and have been scaled by 93.3%.
The cyclotron masses were determined for sample #1 by Lifshitz-Kosevich fits to the temperature dependence of the Fermi velocity of 4.2 eVÅ was measured, by ARPES, at the corners of the nonmagnetic Fermi surface, and 4.9 eVÅ at the faces [16]. If an isotropic Fermi velocity of 4.6 eVÅ is taken along the perimeters of the α, β, γ, and δ orbits, masses of 0.34, 0.63, 1.00, and 1.53me are obtained, respectively: the cyclotron masses from the Lifshitz-Kosevich fits are in very close agreement with the ARPS estimates for α and δ, and ~35% heavier for β and γ.3 Also shown in Fig. 2 are the PdCoO2 frequencies from the parametrized model in Ref. [10], for comparison with PdCrO2. To make the comparison, the PdCoO2 frequencies need to be scaled by the square of the ratio of in-plane lattice constants. We found that the best match is obtained with a scaling of 93.3%, which is very close to the expected scaling (2.830 Å/2.923 Å)2 = 93.7% [1,20,24]. From the comparison it is apparent that the lower branch of the PdCoO2 frequencies, arising from the neck orbit (i.e., the kz = ±π orbit), is visible in the PdCrO2 data, while the upper branch, from the belly orbit (kz = 0), is not. This feature is part of a pattern that extends to the other frequencies: the observed breakdown frequencies derive from reconstruction of the nonmagnetic neck orbit, while the observed fully reconstructed frequencies derive mainly from the belly orbit. The pattern is illustrated in Table 1, which shows the observed PdCrO2 frequencies (for θ → 0) and the expected frequencies based on reconstruction of the PdCoO2 neck and belly orbits: the neck reconstruction yields the observed β and δ frequencies, and the belly reconstruction αγ and γ. (The α frequencies comprise three subbands α1, α2, and α3; we will discuss this in more detail in the following.) What this pattern means is that the belly orbit sees the magnetic order more strongly than the neck orbit. This is not surprising: the Cr sites are midway between the Pd sheets amplitudes. We analyzed the data between 7.5 and 11.5 T, avoiding higher fields where torque interaction was very strong, and verified that within this range there was no systematic variation of the masses with field. The masses obtained for the α, β, γ, and δ orbits are (0.33 ± 0.01), (0.84 ± 0.01), (1.37 ± 0.02), and (1.55 ± 0.04)me, respectively; the fits are shown in the Appendix. These are in good overall agreement with ARPES measurements. A Fermi velocity of 4.2 eVÅ was measured, by ARPES, at the corners of the nonmagnetic Fermi surface, and 4.9 eVÅ at the faces [16]. If an isotropic Fermi velocity of 4.6 eVÅ is taken along the perimeters of the α, β, γ, and δ orbits, masses of 0.34, 0.63, 1.00, and 1.53me are obtained, respectively: the cyclotron masses from the Lifshitz-Kosevich fits are in very close agreement with the ARPS estimates for α and δ, and ~35% heavier for β and γ.3

1While measuring the angle dependence of the oscillations in sample #1, we performed a “de-Gauss” routine at the start of each run, in which the field was ramped to −2 T, then +1 T, then −0.5 T, and so on. The aim was to reduce the probability of the system evolving gradually into a more ordered state, with larger oscillation amplitudes, though it is not clear whether the procedure had much effect.

2Some additional peaks appear in the data, between the β and γ frequencies, and are plotted in the figure. It was not obvious in the raw data whether they were real peaks, interaction peaks, or spurious; they are probably spurious.

3For calculation of the α and γ expected masses, we use the α1 and γ1 orbits.

At θ = 0, and expected frequencies from two-dimensional √3 × √3 reconstruction of the PdCoO2 k0 = 0 and kπ = ±π orbits. Boldface indicates a better match to observations. In the calculations, the PdCoO2 frequencies are scaled by 93.3%, and avoided crossings at band crossings are neglected (apart from their effect on Fermi surface topology).
FIG. 4. (Color online) Left: a possible magnetic cell for PdCrO$_2$, that contains 6 Cr sites. The Cr sites are colored black, gray, and white to indicate the three spin directions of each layer. Right: the nonmagnetic first Brillouin zone (black), together with the PdCoO$_2$ Fermi surface and the six-site zone, into which the nonmagnetic Fermi surface is reconstructed.

(which dominate conduction), and the $k_z = \pm \pi$. Bloch states have zero weight at the planes of the Cr nuclei.

It would be interesting to determine whether coupling to the Cr spins affects the quasiparticle masses. The observed $\delta$ orbit, located at $k_z = \pm \pi$ and with mass $(1.55 \pm 0.04) m_s$, has a very similar mass to the equivalent orbit in PdCoO$_2$, $(1.45 \pm 0.05) m_s$ [10]. So, apparently, at $k_z = \pm \pi$ the cyclotron mass is not strongly affected by the Cr magnetism. The situation at $k_z = 0$, where the coupling to the Cr spins is stronger, is not clear. The observed $\gamma$ orbit, which is at $k_z = 0$, has the $\sim 35\%$ mass enhancement noted earlier; but so does the observed $\beta$ orbit, which is located at $k_z = \pm \pi$.

Overall, then, a two-dimensional $\sqrt{3} \times \sqrt{3}$ reconstruction of the PdCoO$_2$ frequencies, where the reconstruction is weak at $k_z = \pm \pi$, gives a good description of the PdCrO$_2$ frequencies at $\theta = 0$. We now test the reconstruction at other field angles by performing a three-dimensional reconstruction.

We first need a three-dimensional magnetic cell. It must contain at least six Cr sites: three per layer to capture the 120° Néel order, and two layers to capture the alternating vector chirality. The cell we test is shown in Fig. 4. The Cr sites are stacked rhombohedrally, so at $T_N$ there are three equivalent choices for the interplane ordering vector. In choosing one of them, the lattice symmetry is reduced. The space group of the nonmagnetic lattice is $R\bar{3}m$. The highest-symmetry possible magnetic lattice has space group $C2/c$ (base-centered monoclinic); reflection about the glide plane indicated in Fig. 4 reverses the vector chirality within each layer, and translation along the interplane ordering vector restores the original lattice.

FIG. 5. (Color online) Red circles: calculated frequencies based on reconstruction of the PdCoO$_2$ Fermi surface into the magnetic zone shown in Fig. 4. The upper and lower panels show the $\gamma$ and $\alpha$ frequencies, respectively. In the lower panel, the diameter of the symbols is proportional to the logarithm of the expected oscillation amplitude, based solely on the curvature of the Fermi surfaces. Black circles: the frequencies observed in sample #1, with the diameter of the symbols proportional to the logarithm of the amplitude.

Magnetostructural coupling should lead to a lattice distortion associated with the reduction in symmetry, and it is possible that more subtle features in the magnetic order reduce the symmetry further.

The reconstruction is performed as described in textbooks: sections of the nonmagnetic Fermi surface are translated by combinations of reciprocal lattice vectors of the reduced zone until all portions of the original surface are represented within the reduced zone. For our nonmagnetic surface, we take the parametrized model for the PdCoO$_2$ Fermi surface that was determined in Ref. [10]. The topology of the reconstructed Fermi surfaces is determined by the orientations of the avoided crossings that would occur in the real system, but the calculation does not include finite avoided crossings. Further details of the calculation are given in the Appendix. Our results are shown in Fig. 5, together with the observed frequencies.

There are two $\gamma$ bands. The lower band $\gamma_1$ derives from reconstruction of the belly orbit, and $\gamma_2$ the neck orbit. $\gamma_2$ is not observed in the data because the magnetic coupling is weak for the neck orbit.

$^4$In Refs. [6] (LiCrO$_2$) and [1] (PdCrO$_2$), single-crystal neutron scattering data are analyzed using an 18-site magnetic cell. This is the smallest that can preserve $R\bar{3}m$ symmetry: to preserve $R\bar{3}m$ symmetry the interplane ordering vector must take on all three possibilities in an ABCABC order, so six layers are required to capture both this and the alternating vector chirality. The most-likely magnetic structure that is obtained in Ref. [1] can be reduced to a six-site magnetic cell.

$^5$The unit cell shown in Fig. 4 is metrically triclinic (none of the angles are 90°) but if the glide symmetry is preserved, then a 12-site monoclinic supercell can be constructed.
Three α bands appear in the data. The lower and upper bands α₁ and α₃ are reproduced well by the calculation. α₃ is from the nonmagnetic belly orbit and α₁ the neck orbit, so α₁ has a much lower amplitude in the data. The middle band α₂ is not reproduced in the calculations. It could be a breakdown orbit. There are prominent breakdown orbits in the data (β and δ), and the ×2 interplane reconstruction could lead to breakdown orbits that mix segments from the original neck and belly orbits.

For this calculation, we supposed that the system chose the interplane ordering vector that aligned the plane of (possible) glide symmetry with the field rotation plane. The other two possibilities would lead to the glide and rotation planes being separated by 120°. We also calculated this possibility, with the result shown in the Appendix. The match to the data is reasonable but not as good, so it appears that either the glide and rotation planes were aligned by chance, or the fields applied during the measurement reoriented the magnetic reconstruction.

We also show in the Appendix results for a strictly two-dimensional reconstruction, that would preserve the R̅3̅m symmetry of the nonmagnetic lattice. The results do not match the data well, and we conclude that the dominant magnetic scattering vectors are those of the magnetic cell shown in Fig. 4.

III. SPIN-FLOP TRANSITION

In addition to quantum oscillations, a large-scale feature appeared during the torque magnetometry measurements on sample #1: a first-order magnetic transition. It occurs at a field of around 6.5 T for θ = 90° (i.e., the field applied in the plane). On the high-field side of the transition, the sample has a much larger c-axis magnetic moment than on the low-field side. Figure 6 shows the set of torque curves obtained in this study, divided by the applied field to yield $M_⊥$, the magnetization perpendicular to the applied field, and smoothed so as to exclude the oscillations and show broad-scale features. The transition and its hysteresis are readily apparent, at θ ~ 90°. It appeared for sample #1 but not #2, so it is sensitive to the direction of the applied field.

Over a small angle range, quantum oscillations were visible both below and above the transition; the Fourier transforms are shown in the Appendix. At each angle within this range, the oscillations have a lower amplitude on the high-field side of the transition than on the low-field side, and the dominant peak shifts to a slightly higher frequency. That the transition affects the oscillations in a consistent manner shows that it is a bulk property.

This transition is at a similar field to a spin-flop transition reported for CuCrO₂ [21], 5.3 T for temperatures well below $T_N$, and probably has the same origin. In CuCrO₂, it has been found by single-crystal neutron diffraction that the spins lie in ⟨0001⟩-(1100) planes [5,22,23]. The transition occurs when the field is applied in a ⟨1100⟩ direction, but there is no

$^6$Ok et al. also identify three α bands [14]. However, the frequencies they label α₁ and α₂ are both part of α₃ in our labeling scheme, and Ok et al. do not resolve the frequency we label α₁.

FIG. 6. Perpendicular magnetization against applied field at 0.7 K, for sample #1, where the field was rotated in a ⟨0001⟩-(1100) plane. Each curve is offset by the field angle θ; the offsets are indicated by the thin horizontal lines at the left and the angle scale is on the right. The solid lines show downward field sweeps, the dashed lines upward. The curves are smoothed, to exclude quantum oscillations.

FIG. 7. An illustration of the spin flop. In zero field, the spins lie in ⟨0001⟩-(1100) planes (left panel). When a field is applied in a ⟨1100⟩ direction, the spin plane rotates by 90° (right panel). Note that in PdCrO₂ the spins are not perfectly coplanar; see Ref. [1] for details. Also, there may be domains of different ⟨0001⟩-(1100) spin planes; the evolution of each possible domain with applied in-plane field is discussed in Ref. [21].
For PdCrO₂, although observation of an unconventional anomalous Hall effect shows that the spins are not coplanar, neutron scattering data show that the spins lie approximately in a (0001)-⟨1100⟩ plane, similar to CuCrO₂. Furthermore, and also as in CuCrO₂, the transition occurs when the field is applied in a (1100) direction (sample #1), but not in a (1000) direction (#2). Therefore, the transition is probably the same spin flop.

IV. RESISTIVITY

PdCoO₂ has been used as a nonmagnetic analog of PdCrO₂ in order to extract the magnetic contribution to the specific heat and electrical resistivity [8,13]. We have shown here that it is a very good comparison: the PdCrO₂ Fermi surfaces are, to high precision, a reconstruction of the PdCoO₂ Fermi surface, and the cyclotron masses match closely.

The in-plane resistivity of PdCoO₂ is substantially nonlinear between ~100 and 500 K, a feature attributed to prominent optical phonons [24]. The resistivity of PtCoO₂ also shows this feature [25]. We include in this paper data on the resistivity of PdCrO₂ up to 500 K, in order to extend the comparison reported in Ref. [13] to higher temperatures and to see whether the same feature appears in PdCrO₂.

All samples for resistivity measurement were cut with a wire saw into bars of nearly constant width and thickness, and with length-to-width ratios of ~10, to reduce geometrical uncertainties in conversion of resistance to resistivity. Our data are plotted in Fig. 8. We measured one PdCoO₂ and two PdCrO₂ samples, labeled A and B; sample A had two pairs of voltage contacts, so in total three PdCrO₂ curves were recorded. Averaging the three measurements, the room-temperature (295 K) resistivity of PdCrO₂ was found to be 8.2 ± 1.0 μΩ cm, where the uncertainty is from uncertainty in the sample dimensions. This is in good agreement with that reported in Ref. [13], 9.4 μΩ cm.

The form of the resistivity of PdCrO₂ is well established. There is a sharp cusp at T_N, and above T_N the magnetic component of the resistivity ρ_m remains well below its saturation value due to short-range correlation. The increase and eventual saturation of ρ_m as the temperature increases leads to a convex temperature dependence of the resistivity.

The in-plane resistivity of PdCrO₂, in contrast to PdCoO₂ and PtCoO₂, is essentially linear from ~200 to at least 500 K. It may be that the temperature dependence of ρ_m obscures an optical phonon contribution. ρ_m is expected to saturate when the Cr spins become completely uncorrelated. If ρ_m is estimated by subtracting the resistivity of PdCoO₂ from that of PdCrO₂, then our data indicate that ρ_m continues to increase at temperatures well above room temperature, i.e., ρ_m continues to evolve to temperatures an order of magnitude greater than T_N. The Weiss temperature of PdCrO₂ is ~−500 K [8], so correlations between the Cr spins are expected to persist to temperatures up to ~500 K, and a high saturation temperature of ρ_m may be expected.

V. DISCUSSION AND CONCLUSION

The quantum oscillation frequencies indicate that the dominant magnetic scattering vectors are those of a six-site magnetic cell with lower symmetry than the nonmagnetic lattice. An associated lattice distortion is expected to onset at T_N. It has been looked for by both neutron and x-ray diffraction, and not found [1], so any distortion must be small.

The distortion, if it occurs, should resemble that observed in CuCrO₂ [26]; there is also evidence for a lattice distortion in AgCrO₂ [27]. In CuCrO₂, the vector chirality is the same in each layer and the magnetic cell contains three sites [2,4,5].

The magnetic transition is split into two [28], which is expected for easy-axis-type 120° antiferromagnetism: spins first order along the easy axis, then, at a lower temperature, along an in-plane axis. Ultrasound velocity measurements show that the lattice distortion starts at the upper transition, with no apparent anomaly at the lower transition [28].

The transition of PdCrO₂ may also be split, although if so the splitting is small and not generally observed in experiment [1]. Either way, the magnetic order implies two separate reductions in symmetry from R3m: the choice of interplane ordering vector at the (possible) upper transition, and the choice of spin plane at the lower transition (where, again, in PdCrO₂ the spins are only approximately coplanar). The two symmetry reductions are likely to couple. The ultrasound data on CuCrO₂ suggest that in that system it is the interplane ordering vector that more strongly drives the distortion.

The angle dependence of the spin-flop transition in PdCrO₂ is interesting: the transition field appears to vary smoothly from ~15 T on one side of the plane (at θ ~ +55°) to nearly zero on the other (at θ ~ −55°). At B = 0, however, the field angle is a meaningless parameter, so if there is in fact an end point near B = 0, then the high- and low-field states are adiabatically connected to each other. Whether this is true and how it might occur for a 90° spin flop requires further investigation.

In summary, PdCrO₂ is an interesting system comprised of alternating highly conductive sheets and Mott-insulating spacer layers. It provides a good model for study of the interaction between metallic conduction and antiferromagnetic

FIG. 8. The resistivity of PdCrO₂ against temperature, for two samples. Sample A had two pairs of voltage contacts. The point at 295 K, with error bars, indicates the room-temperature resistivity: 8.2 ± 1.0 μΩ cm. Data on a PdCoO₂ sample are also shown, scaled to the room-temperature resistivity determined in Ref. [10]: 2.6 ± 0.2 μΩ cm. Bottom panel: dρ/dT for sample A.
order: the conduction is well characterized, arising from a single, open Fermi surface, and much is known about the magnetic order. Also, there are related compounds that permit precise comparisons, such as the nonmagnetic PdCoO$_2$, and other CrO$_2$-based delafossite and ordered rock-salt materials. Several avenues of inquiry remain open.

APPENDIX

In this Appendix we first present some supplementary data, and then give further details on the calculation of the three-dimensional reconstruction.

Figure 9 shows the Lifshitz-Kosevich fits to the oscillation amplitudes determined over the field range 8.5–9.5 T. Four such fits were done, over 1-T field ranges starting at 7.5, 8.5, 9.5, and 10.5 T. The masses reported in the main text are the averages of the masses obtained from these fits.

Figure 10 shows the Fourier transforms of the oscillations above and below the putative spin-flop transition, for the narrow angle range over which oscillations were observed on both sides of the transition. On the high-field side of the transition, the oscillations have lower amplitudes and the main peak a higher frequency. (The reduction in amplitude may not be immediately apparent in the figure, but normally quantum oscillation amplitudes grow rapidly as the field is increased, and the reduction in amplitude is very clear in the raw data.)

We now give further details on the reconstruction. The first step is to determine the misalignment, if any, between the sample and the field angle sensor mounted on the rotator platform. This misalignment is determined, for sample #1, by comparison of the observed $\delta$ frequencies and the scaled PdCoO$_2$ frequencies, shown in Fig. 2. The best match is obtained when a $0.3 \pm 0.2^\circ$ offset is added to the measured field angle. This is our misalignment, and correction for it is incorporated into all plots of sample #1 frequencies presented in this paper.

We take the nonmagnetic Fermi surface to be the parametrized PdCoO$_2$ Fermi surface that was determined in Ref. [10]. The parameters specifying the Fermi surface are the radius of a circular, cylindrical base Fermi surface $k_{00}$, and then the amplitudes of the corrugations on this base. $k_{60}$, for example, is the amplitude of the hexagonal distortion. $k_{01}$ sets the difference between the radii of the neck and belly orbits. A thorough description of this system of parametrization is given in Ref. [29].

We allow three parameters to be adjusted, within small ranges that are consistent with experiment, to match the overall levels of the observed PdCrO$_2$ frequencies. We emphasize that this adjustment only tunes the overall levels, and does not substantially alter any of the substructure. These parameters are as follows: (1) the overall size of the Fermi surface ($k_{00}$), (2) the magnitude of the hexagonal distortion ($k_{60}$), and (3) the in-plane lattice constant $a$. The $k_z$-dependent Fermi surface corrugations ($k_{01}, k_{02},$ and $k_{31}$) are left fixed at the amplitudes found for PdCoO$_2$. When $k_{60}$ is adjusted, the higher-order
amplitudes $k_{12,0}$ and $k_{18,0}$ are adjusted by hand in response, to smooth the faces and sharpen the corners of the Fermi surface so as to match the Fermi surfaces observed by ARPES [15,16].

The best match is found with $k_{00} = 0.9219 \, \AA^{-1}$, $k_{a0} = 0.036 \, \AA^{-1}$, and $\alpha = 2.927 \, \AA$. Further refinement (for example, by allowing a low-temperature lattice distortion, or modification of the $k_{z}$-dependent corrugations, or finite avoided crossings) might yield slightly different results: the obtained lattice parameter, for example, is not precisely in line with expectations, as it has been measured to be 2.923 \, \AA at room temperature and some thermal contraction is expected [1]. However, these fitting parameters are within bounds permitted by experiment and are adequate to model the angle dependence.

In addition to the reconstruction shown in the main text, we tested two further possibilities. The first is the same reconstruction but with the other possible orientation relative to the field rotation plane, that the glide plane is rotated from the field rotation plane by 120°. The second tests a hypothetical magnetic zone with vertical side walls, that would preserve the $R3m$ symmetry of the nonmagnetic lattice. The results are shown in Fig. 11.

The rotated reconstruction, shown in the left-hand panels in Fig. 11, gives a reasonable match to the data, but not as good as with the glide and rotation planes aligned: it yields the wrong sign on the slope of $\alpha_1$ against $\theta$, and too low an amplitude on the substructure of the $\gamma_1$ frequencies. The $R3m$ reconstruction gives a worse match: although it reproduces the $\alpha_1$ and $\alpha_3$ frequencies reasonably well, it does not reproduce the structure on $\gamma_1$ at all. Therefore, we conclude that the magnetic reconstruction illustrated in Figs. 4 and 5 is the correct one.

[19] The cantilevers are model PRC120, from Seiko Precision Instruments. The sense element is piezoresistive, and the data sheet lists the response, at room temperature, as 16.5 Ω/μm. The spring constant is $\approx 40$ N/m, and the length 120 μm; these parameters can be combined to yield a response to torque of $\approx 3 \times 10^5$ Ω/m.
