A Synthetic Pseudo-Rh: NO\textsubscript{x} Reduction Activity and Electronic Structure of Pd–Ru Solid-solution Alloy Nanoparticles

Katsutoshi Sato\textsuperscript{1,2}, Hiroyuki Tomonaga\textsuperscript{2}, Tomokazu Yamamoto\textsuperscript{3}, Syo Matsumura\textsuperscript{4,5}, Nor Diana Binti Zulkifli\textsuperscript{5}, Takayoshi Ishimoto\textsuperscript{4}, Michihiro Koyama\textsuperscript{4,5}, Kohei Kusada\textsuperscript{6}, Hirokazu Kobayashi\textsuperscript{6}, Hiroshi Kitagawa\textsuperscript{4,6} & Katsutoshi Nagaoka\textsuperscript{2}

Rh is one of the most important noble metals for industrial applications. A major fraction of Rh is used as a catalyst for emission control in automotive catalytic converters because of its unparalleled activity toward NO\textsubscript{x} reduction. However, Rh is a rare and extremely expensive element; thus, the development of Rh alternative composed of abundant elements is desirable. Pd and Ru are located at the right and left of Rh in the periodic table, respectively, nevertheless this combination of elements is immiscible in the bulk state. Here, we report a Pd–Ru solid-solution-alloy nanoparticle (Pd\textsubscript{x}Ru\textsubscript{1-x}NP) catalyst exhibiting better NO\textsubscript{x} reduction activity than Rh. Theoretical calculations show that the electronic structure of Pd\textsubscript{0.5}Ru\textsubscript{0.5} is similar to that of Rh, indicating that Pd\textsubscript{0.5}Ru\textsubscript{0.5} can be regarded as a pseudo-Rh. Pd\textsubscript{0.5}Ru\textsubscript{0.5} exhibits better activity than natural Rh, which implies promising applications not only for exhaust-gas cleaning but also for various chemical reactions.
because binary combinations of Pd-Ru are well known to be immiscible at the atomic level and form segregated domain structures in the bulk at all temperatures up to their melting points\textsuperscript{19–21}. Recently, Kusada et al. have successfully synthesized Pd-Ru NPs over the entire compositional range via a chemical reduction method based on “non-equilibrium synthesis” and “nano-size effect”\textsuperscript{22}. In the work, solid solution alloying of Pd and Ru enhanced several properties of NPs. However, it is not uncovered whether Pd-Ru NPs show comparable catalytic performance to that of Rh in the reaction which is invaluably catalysed by Rh. Therefore, the application of the Pd-Ru NPs for NO\textsubscript{x} reduction is interesting. Here, we report the Pd\textsubscript{0.5}Ru\textsubscript{0.5} NPs catalyst exhibiting excellent NO\textsubscript{x} reduction activity, which is a most crucial properties of three-way catalysts\textsuperscript{1,2,11,12}, with its electronic structure similar to that of Rh. In other words, Pd\textsubscript{0.5}Ru\textsubscript{0.5} NPs behave like synthetic pseudo-Rh. This strategy is in line with direction of “elements strategy” driven in the world\textsuperscript{23}.

### Results

#### Preparation of Pd\textsubscript{x}Ru\textsubscript{1-x} NPs and supported catalysts.

Pd\textsubscript{x}Ru\textsubscript{1-x} NPs were synthesized via a previously reported chemical reduction method using Pd and Ru precursors. Monometallic Pd, Ru, and Rh NPs were also prepared using the same procedure. The Pd\textsubscript{x}Ru\textsubscript{1-x} NPs were deposited onto γ-Al\textsubscript{2}O\textsubscript{3} supports (Fig. 1a) via a standard impregnation method\textsuperscript{22}. High-angle annular dark-field scanning transmission electron microscopy (HAADF–STEM) image and elemental maps using energy-dispersive X-ray spectroscopy (EDX) of the γ-Al\textsubscript{2}O\textsubscript{3}-supported Pd\textsubscript{0.5}Ru\textsubscript{0.5} NPs are shown in Fig. 1. As shown in Fig. 1a, a few primary NPs are forming small secondary particles and those secondary NPs were well dispersed over γ-Al\textsubscript{2}O\textsubscript{3} support. Figure 1b shows a magnified view of loaded NPs. One can find the overlap of NPs that appear as brighter region in the figure. In addition, the EDX maps of Pd, Ru, and their superpositions (Fig. 1c–e) reveal that Pd and Ru atoms were homogeneously dispersed throughout the NPs. Crystalline structure of Pd\textsubscript{0.5}Ru\textsubscript{0.5} NPs are confirmed to be fcc-rich, but contains hcp phase also. As the Pd ratio in Pd\textsubscript{x}Ru\textsubscript{1-x} increases, fcc phase becomes more dominant. Charge transfer from Pd to Ru at the surface of Pd\textsubscript{x}Ru\textsubscript{1-x} alloy was also demonstrated by X-ray photoelectron spectroscopic measurement. Further details are reported elsewhere\textsuperscript{22}.

#### Catalytic performance for NO\textsubscript{x} reduction.

To investigate the catalytic activity of the Pd\textsubscript{0.5}Ru\textsubscript{0.5} NPs for NO\textsubscript{x} reduction, we carried out activity tests using a fixed-bed flow reactor. Pelletized γ-Al\textsubscript{2}O\textsubscript{3}-supported Pd\textsubscript{0.5}Ru\textsubscript{0.5} NPs were packed into a tubular reactor, and we supplied a reaction mixture simulating automotive exhaust with a theoretical air-to-fuel ratio such that the CO and the C\textsubscript{3}H\textsubscript{6} in the fuel were stoichiometrically combusted by NO and O\textsubscript{2}. The catalyst bed was heated from ambient temperature to 600 °C at a constant rate of 10 °C min\textsuperscript{−1}, and the effluent gas was analysed during the heating. For comparison, γ-Al\textsubscript{2}O\textsubscript{3}-supported Pd, Ru, and Rh NPs were also tested under the same conditions (Fig. 2). The NO\textsubscript{x} conversion rate for Pd\textsubscript{0.5}Ru\textsubscript{0.5}, Ru, and Rh NPs increased smoothly with increasing temperature. By contrast, the Pd NPs exhibited a small peak in their conversion rate at 250 °C, followed by an increase in activity starting from approximately 300 °C, as has been frequently reported in previous studies\textsuperscript{24,25}. An inspection of Fig. 2 reveals that the Pd\textsubscript{0.5}Ru\textsubscript{0.5} NPs exhibited equal or greater NO\textsubscript{x} reduction activity when compared with Rh NPs, which have been considered the most active NO\textsubscript{x} reduction catalyst. At low temperatures, in particular, the Pd\textsubscript{0.5}Ru\textsubscript{0.5} NPs exhibited excellent NO\textsubscript{x} reduction activity that exceeded that of the Rh NPs. The temperatures corresponding to 50% NO\textsubscript{x} conversion (T\textsubscript{50}) for the Pd\textsubscript{0.5}Ru\textsubscript{0.5}, Rh, Ru, and Pd NPs were 180, 193, 282, and 344 °C, respectively, demonstrating that the Pd\textsubscript{0.5}Ru\textsubscript{0.5} NPs exhibited the highest NO\textsubscript{x} reduction activity among the investigated catalysts. Influence of reaction temperature on concentrations of gasses containing nitrogen atom is displayed in Supplementary Fig. S1. N\textsubscript{2}O was major product and NO\textsubscript{x} was almost completely converted to N\textsubscript{2} above 350 °C. In addition, N\textsubscript{2}O was also produced from 200 °C. Selectivity of N\textsubscript{2}O increased with increase in the temperature by 250 °C but decreased gradually above the temperature. The catalytic

activity of the physical mixture of Pd and Ru (0.5 wt% of Ru NPs and 0.5 wt% of Pd NPs) was also measured for comparison (Supplementary Fig. S2); these mixed NPs exhibited slightly better NOx reduction activity than the unmixed, single-component Pd and Ru NPs. However, the temperature dependence of the catalytic activity for the physical mixture of NPs differed from that of the Pd0.5Ru0.5 NPs and the activity of the mixture was substantially lower than that of the Pd0.5Ru0.5 NPs. These results demonstrate that the atomic-level alloying of Pd and Ru in the NPs plays a key role in the emergence of their excellent NOx reduction activity.

Electronic structure of Pd0.5Ru0.5 NPs. The dissociative chemisorption of NO is well known to be the first step in NO reduction and is also known to be favoured on the Rh surface21,22. Both the electron donation from the NO σ orbital to the Rh 4d orbital and the electron back-donation from the Rh 4d orbital to the anti-bonding NO 2π orbital, which lead to weakening of the NO bond, have been reported to be important for the activation of the NO molecule for dissociation26–28. Therefore, we used first-principles methods to investigate the electronic structure, i.e., the density of states (DOS), of the Pd0.5Ru0.5 alloy system and the Rh, Pd, and Ru NP systems (Fig. 3). The Rh energy band ranges from approximately +1 eV to −6 eV, with a maximum peak intensity of approximately 3 electrons/eV and three characteristic peaks at +0.39, −2.58, and −5.07 eV. These features are clearly observed in the Pd0.5Ru0.5 band structure, which differs substantially from those of the Pd and Ru systems. Estimation of d-band center in relative to Fermi energy was −2.866 and −2.821 eV for Pd0.5Ru0.5 and Rh, respectively, while those for Pd and Ru are estimated as −2.306 and −3.075 eV, respectively. Inspection of the
partial DOS of Pd and Ru in the Pd_{0.5}Ru_{0.5} NPs readily shows that the alloying does not result in a simple linear combination of the electronic structures of Pd and Ru but rather gives rise to an Rh-like electronic structure (Supplementary Fig. S3). This result indicates that the Pd_{0.5}Ru_{0.5} alloy can be regarded as a pseudo-Rh in terms of its bulk electronic structure, which should lead to a high catalytic activity similar to that of Rh. Furthermore, the similarity between the Rh and Pd_{0.5}Ru_{0.5} DOS observed here suggests that the DOS of a target monometal can be reproduced via the alloying of other elements. To see the correlation between Rh-like electronic structure and the NOx reduction activity, NO adsorption properties onto fcc Pd_{0.5}Ru_{0.5}(111) as well as Rh(111) are investigated as a first step to screen the activity toward NO molecule. Supplementary Fig. S4 shows the relation between the NO adsorption energy and the N-O bond distance. Compared to the N-O distance of gas phase NO molecule, i.e. 1.172 Å, elongations of N-O distance is observed for all the cases investigated, indicating the activation of NO molecule for the decomposition. Four points for NO adsorption on Rh(111) surface correspond to ontop, bridge, fcc-3-fold, and hcp-3-fold sites, respectively. One can see a general tendency that activation is more evident for bridge than ontop, 3-fold than bridge site adsorption, corresponding to the stronger backdonation in such order. NO adsorption properties on Pd_{0.5}Ru_{0.5} shows a complex feature. NO adsorption on Pd ontop site is weaker in adsorption energy and Ru ontop is stronger, while the adsorption on both ontop sites are associated with only a slight activation of NO molecule in terms of N-O distance. For other cases of bridge and hollow-site adsorption, we can see a general trend like Rh, i.e. stronger adsorption energy is associated with the higher activation of NO molecule. Further, it is noted that we can find greater activations of NO molecule on Pd_{0.5}Ru_{0.5} at a certain configuration investigated.

Influence of Pd–Ru composition on catalyst performance. To investigate the influence of the Pd_{x}Ru_{1-x} composition on the NPs’ activity towards NOx reduction, we carried out activity tests using γ-Al_{2}O_{3}-supported Pd_{x}Ru_{1-x} NPs with various Pd–Ru compositions (x = 0, 0.1, 0.3, 0.5, 0.7, 0.9, 1) (Fig. 4a). Note that mean diameters of the alloy NPs investigated are in the similar range, i.e. ca. 10 nm, except for the Ru as shown in Supplementary Table S1. The T_{50} for NOx conversion observed for all of the Pd_{x}Ru_{1-x} NPs was lower than those of the monometallic Pd and Ru NPs (Fig. 4b). Thus, these results reveal a positive alloying effect over the whole solid-solution composition range. Furthermore, the NOx reduction activity of the Pd_{x}Ru_{1-x} NPs changes continuously with the atomic ratio of Pd and Ru, showing an inverse volcano-type behaviour. In particular, Pd_{0.5}Ru_{0.5} with x = 0.5 and 0.7 exhibited excellent NOx reduction activities that exceeded that of Rh. DOS of Pd_{0.5}Ru_{0.5} in Supplementary Fig. S5 shows that features of DOS of Rh, i.e. band width, positions and intensities of three characteristic peaks, are retained in the composition calculated. As reported in the preceding work, the fcc phase becomes richer as the

![Figure 4](https://www.nature.com/scientificreports/)
Pd composition in Pd$_{x}$Ru$_{1-x}$ increases. In addition, the DOS of hcp phase of Pd$_{x}$Ru$_{1-x}$ is different from that of Rh as shown in Supplementary Fig. S3. Thus, the high activity of Pd$_{x}$Ru$_{1-x}$ with $x = 0.5$ and 0.7 can be interpreted to originate from the similarity of DOS of Pd$_{0.5}$Ru$_{0.5}$ in fcc phase, while we admit the potential complex factors behind the observed activity. It is well known that the commodity prices of Pd and Ru are substantially lower than that of Rh$^9$, thus Pd$_{x}$Ru$_{1-x}$ can contribute to the cost reduction of NO$_x$ reduction catalyst system. Considering that the price of Ru is lower than Pd, Pd$_{0.5}$Ru$_{0.5}$ NPs represent a promising new NO$_x$ reduction catalyst that costs one-third as much as Rh. A drastic activity enhancement in the case of the Pd$_{x}$Ru$_{1-x}$ NPs was also observed for the elimination of CO and hydrocarbon (C$_3$H$_6$), which are other major pollutants in exhaust emissions (Supplementary Figs S6, S7).

Conclusion

In summary, we developed Pd$_{x}$Ru$_{1-x}$ NPs with excellent NO$_x$ reduction activity compared to that of Rh, which is currently the most active and widely used NO$_x$ reduction catalyst. DOS features similar to those of the Rh DOS were observed for bulk Pd$_{0.5}$Ru$_{0.5}$, indicating that the catalytic activity of Pd$_{0.5}$Ru$_{0.5}$ towards NO$_x$ reduction is a consequence of its Rh-like electronic structure. These findings predict that Pd$_{x}$Ru$_{1-x}$ NPs have potential applications as catalysts for various reactions currently catalysed by Rh. The alloying of immiscible elements provides a new direction for the design of novel materials for simultaneous enhancement of catalytic activity and reduction of the materials costs. Our concept of designing materials with desirable and suitable properties via the atomic-level mixing of elements was demonstrated for Pd$_{x}$Ru$_{1-x}$ NPs, and this approach should be applicable to numerous other combinations of elements and various classes of catalytic reactions, thereby initiating a new scientific field of study.

Methods

Synthesis of NPs and supported catalysts. For a typical synthesis of Pd$_x$Ru$_{1-x}$ NPs ($x = 0.5$), poly(N-vinyl-2-pyrrolidone) (PVP, 444 mg, MW ≈ 40 000, Wako) was dissolved in triethylene glycol (TEG, 100 mL, Wako) and the resulting solution was heated to 200 °C under magnetic stirring. Meanwhile, K$_2$[PdCl$_4$] (163.4 mg, Aldrich) and RuCl$_3$·nH$_2$O (131.1 mg, Wako) were dissolved in deionized water (40 mL). The resulting aqueous solution was then slowly added to the TEG solution, which was maintained at 200 °C during the addition for 20 to 40 min. After cooling to room temperature, the prepared NPs were separated by centrifugation. Other Pd$_{x}$Ru$_{1-x}$ NPs ($x = 0.1, 0.3, 0.7, 0.9$) were prepared by controlling the molar ratio between Pd$^{2+}$ and Ru$^{3+}$ ions.

Ru, Rh, Pd, and Pd$_{x}$Ru$_{1-x}$ alloy NPs and a physical mixture (Ru and Pd NPs) supported on γ-Al$_2$O$_3$ catalysts were prepared by wet impregnation. Each NP sample (equivalent to 1 wt% of γ-Al$_2$O$_3$) was ultrasonically dispersed in purified water. A high-purity γ-Al$_2$O$_3$ support (AKP-GO15, Sumitomo Chemical) that had been precalcined at 800 °C for 5 h was placed into each aqueous NP solution, and the suspended solutions were stirred for 12 h. After being stirred, the suspended solutions were heated to 60°C and then dried under vacuum. The resulting powders were maintained at 120°C for 8 h to completely remove water.

High-resolution TEM (HRTEM), HAADF–STEM, and EDX analyses. Samples were dispersed in ethanol, dropped onto a carbon-coated copper grid, and dried by exposure to ambient conditions for 24 h. HRTEM, HAADF–STEM, and EDX mapping images were collected using a JEM-ARM200F (JEOL) transmission electron microscope operated at 200 kV.

Theoretical calculations. All calculations were performed using the VASP$^{29–32}$. The crystal structures of bulk Rh (fcc), Pd (fcc), Ru (hcp), and Pd$_{0.5}$Ru$_{0.5}$ (fcc/hcp) were reproduced using four-atom unit cells with periodic boundary conditions for both fcc and hcp lattices. We prepared three-layers 2$x$ supercell slab models to study the surface properties. 20 different configurations were prepared for Pd$_{x}$Ru$_{1-x}$ surface model to see the influence of configurations of Pd and Ru on the adsorption properties. For each configuration, all possible adsorption sites are tested as the initial structure. The geometries for bulk Rh, Pd, Ru, and the Pd$_{x}$Ru$_{1-x}$ alloys were optimized under the generalized gradient approximation (GGA) with the Perdew–Burke–Ernzerhof (PBE) exchange-correlation functional$^{33}$. Cut off energy is set to be 400 eV and the projector-augmented wave method$^{34,35}$ is adopted. Monkhorst–Pack k-point grid sampling$^{36}$ was used with the k-points of 14×14×14 and 7×7×7 for optimization of bulk and surface models, respectively. The DOS were analysed with further refined condition with the cut off of 700 eV and k-points of 23×23×23.

Catalytic activity tests. Powders of the γ-Al$_2$O$_3$-supported catalysts were pressed into pellets at 52 MPa for 5 min. They were then crushed and sieved to obtain grains with diameters of 250–500 μm. For each test, 200 mg of catalyst grains was loaded into a tubular quartz reactor (internal diameter = 7 mm), and quartz wool was then packed around the catalyst. In addition, a k-type thermocouple was inserted into the catalyst bed to measure the temperature for feedback control of the system. A feed-gas mixture containing NO (1161 ppm), CO (5750 ppm), C$_2$H$_6$ (467 ppm), O$_2$ (5050 ppm), H$_2$ (1760 ppm), CO$_2$ (12.5%), and He (balance) was passed over each catalyst (total flow rate = 200 mL min$^{-1}$; space velocity = 60 000 h$^{-1}$). The gas mixture was designed to mimic the air-to-fuel ratio of automotive emissions. The catalyst bed was heated from ambient temperature to 600°C at 10°C min$^{-1}$ under the flowing reaction mixture. The outlet gas composition was continuously monitored with a chemiluminescence NO$_x$ analyser (VA3000, HORIBA and Model 42i-HL, Thermo Fisher Scientific), a non-dispersive infrared gas analyser (VA3000, HORIBA), and gas chromatograph (490 Micro GC, Agilent Technologies).
