High-intensity focused ultrasound (HIFU) is a non-invasive therapy commonly used to destroy a targeted area without damaging the surrounding tissue. This thermal ablation therapy has been applied to various diseases, including tumor ablation in the liver, bladder, uterus and prostate. However, there are some limitations regarding the clinical application of HIFU for cancer therapy. First, several HIFU exposures are required to ablate the entire volume because the focal point is only a few square millimeters. Second, sufficient cooling time must be allowed between applications to prevent the ablation of normal tissue surrounding the tumor. Consequently, HIFU treatments involve multiple long sessions that are uncomfortable for the patients. In addition, HIFU is not approved for breast cancer because it causes skin burns around shallow tumors. Most adverse effects are caused by the high acoustic intensity of HIFU. However, the use of lower acoustic power or shorter time exposure would reduce treatment efficacy.

Recent improvements to ultrasound therapy include combinations of HIFU/non-focused ultrasound with microbubbles, nanobubbles or nanodroplets. These bubbles (and droplets after phase changing of nanodroplets) oscillate under lower acoustic power. Thereby, a part of the ultrasound energy is absorbed and changed to heat. Higher acoustic power may lead to collapse of bubbles. This phenomenon, known as cavitation, induces jet streams, heat and the generation of reactive oxygen species, thereby damaging nearby cells. When ultrasound without a focal point is used to irradiate a tissue, the chemical, thermal and mechanical effects are mild compared to HIFU. To enhance these effects with a non-focused ultrasound system, the combination of bubbles and non-focused ultrasound has been studied. Nano-bubbles or micro-bubbles oscillate and disrupt in an ultrasound field, inducing various effects as mentioned above. Generally, these effects can be induced even at low intensity of ultrasound, which has a very small effect without bubbles. Therefore, it is thought that for non-focused ultrasound exposure in the absence of bubbles, there is low risk of tissue damage. Recently, the combination of bubbles and ultrasound has been utilized in thrombosis systems and gene/drug delivery systems. In the field of thermal effects, it was reported that intravenous administration of microbubbles caused a fivefold increase in murine kidney temperature during ultrasound exposure. We recently developed Bubble liposomes (BL) entrapping perfluoropropane gas...
There are various medical applications for these small and stable BL, such as contrast imaging agents and drug and gene delivery. Moreover, we reported that intratumoral injection of BL enhances the anti-tumor effect of HIFU in mice. In the present study, we tested the potential of intratumoral BL and ultrasound (≤ 4 W/cm²) as an effective cancer therapy with reduced adverse effects. In addition, in physical cancer therapies such as radiotherapy and photodynamic therapy, it is suggested that their anti-tumor effects are associated with priming of the systemic immune system for cancer cells. Moreover, low-pressure pulsed focused ultrasound with microbubbles promoted immune cell infiltrations. Therefore, we hypothesized that the combination of intratumoral injection of BL and ultrasound would enhance the anti-tumor effect through a mechanism involving anti-tumor immune responses. In this study, we also studied the effect of cellular immunity on the therapeutic efficacy of BL + ultrasound.

Materials and Methods

Cells and animals. Murine colon adenocarcinoma Colon-26 cells were purchased from RIKEN Cell Bank. Colon-26 cells were grown in RPMI-1640 (Wako Pure Chemical Industries, Osaka, Japan) containing 100 U/mL penicillin (Wako Pure Chemical Industries) and 100 μg/mL streptomycin (Wako Pure Chemical Industries) supplemented with 10% heat-inactivated FBS (Life Technologies, Carlsbad, CA, USA). BALB/c female mice were obtained from Sankyo Labo Service (Tokyo, Japan) and used at 6 weeks of age. All of the experimental procedures were performed in accordance with the Teikyo University guidelines for the welfare of animals in studies of experimental neoplasia.

Preparation of the Bubble liposomes. Liposomes composed of 1,2-distearyoyl-sn-glycero-phosphatidylcholine (DSPC) (NOF, Tokyo, Japan) and N-(Carboxyl-methoxypolyethylene glycol 2000)-1,2-distearyoyl-sn-glycero-3-phosphatidylethanolamine (DSPE-PEG(2k)-OMe) (PEG, Mw = ca. 2000) (NOF) (94:6 mol/mol) were prepared by reverse-phase evaporation. In brief, all reagents (total lipid: 100 μmol) were dissolved in 8 mL of 1:1 (v/v) chloroform/2-propanol. A total of 1 mL of PBS was added, and the mixture was sonicated and evaporated at 65°C. The organic solvent was completely removed, and the size of the liposomes was adjusted to <200 nm using an extruding apparatus (Northern Lipids, Vancouver, BC, Canada) and sizing filters (pore sizes: 100 and 200 nm [Nuclepore Track-Etch Membrane, Whatman, UK]). After sizing, the liposomes were sterilized through a 0.45-μm pore size filter (Milllex HV filter unit; Durapore PVDF membrane, Millipore, MA, USA). The diameter of the liposomes (150–200 nm) was measured by dynamic light scattering (ELS-800; Otsuka Electronics, Osaka, Japan). The lipid concentration was measured with an HPLC system (Hitachi High-Technologies, Tokyo, Japan) and an Evaporative Light Scattering Detector (ASTECH, Tokyo, Japan). The BL were prepared using the liposomes and perfluoropropane (Takachiho Chemical Industrial, Tokyo, Japan). In brief, 5-mL sterilized vials (Maruemu, Osaka, Japan) containing 2 mL of liposome suspension (lipid concentration: 1 mg/mL) were filled with perfluoropropane, capped and supercharged with 7.5 mL of perfluoropropane. The vial was placed in a bath-type sonicator (42 kHz, 100 W; Branson 2510J-DTH, Branson Ultrasonics, Danbury, CT, USA) for 5 min to form BL. The liposomes were reconstituted by sonication and supercharged with perfluoropropane in the vial. Perfluoropropane was entrapped within the lipid micelles, comprising DSPC and DSPE-PEG (2k)-OMe, to form nanobubbles. The perfluoropropane gas nanobubbles were encapsulated within the reconstituted liposomes. The mean diameter of these BL was approximately 500 nm.

Ultrasound exposure in vivo. Sonitron 2000V (Nepa Gene, Chiba, Japan) was utilized as a device for ultrasound exposure in in vivo experiments. This device generates ultrasound from a non-focused ultrasound transducer (diameter: 12 mm). Mechanical index (MI) values utilized in our study were 0.147, 0.207, 0.254 and 0.283 for acoustic intensity of 1, 2, 3 and 4 W/cm², respectively, in 1 MHz. Root mean squared values of sound peak pressure were 0.109, 0.154, 0.188 and 0.217 MPa, respectively. These values were supplied from Nepa Gene.

Tumor inoculation. BALB/c mice were subcutaneously inoculated with Colon-26 tumor cells (1 × 10⁶ cells/mouse) into the flank. After 8 days, we utilized these mice in this experiment as tumor-bearing mice.

Measurements of tumor temperature. Tumor temperature was measured with a thermocouple (RIC-410; GRAPHTEC, Kanagawa, Japan) and data logger (midi LOGGER; GRAPHTEC). First, the thermocouple was inserted into the center of the tumor and anesthetized tumor-bearing mice. Second, a suspension of BL (0.1 mg/mL, 30 μL/mouse) or saline at room temperature was intratumorally injected at the upper side of the thermocouple. Third, ultrasound was transdermally applied via ultrasonic gel (SONOJELLY; Toshiba Medical Supply, Tokyo, Japan) and ultrasound (frequency 1 MHz, duty 50%, burst rate 2 HZ, intensity 0–4 W/cm²) was exposed to the tumor for 2 min. Finally, tumor temperature was recorded at each time point after ultrasound exposure. Under these exposure conditions, no damage to skin or tissue surrounding the tumors was seen.

Histochemical analysis. A suspension of BL (0.1 mg lipid/mL, 30 μL/mouse or saline was injected into the tumor of tumor-bearing mice, and ultrasound (frequency 1 MHz, duty 50%, burst rate 2 Hz, intensity 0–4 W/cm²) was transdermally applied to the tumor for 2 min. After the mice were killed, the tumor tissue was dissected, fixed with 10% formaldehyde for 24 h, embedded in paraffin wax and cut into 10-μm-thick sections. The sections were stained with hematoxylin and eosin stain (H&E) to evaluate general morphology under a light microscope (IX-71, Olympus, Tokyo, Japan).

Anti-tumor effect. A suspension of BL (0.1 mg/mL, 30 μL) or saline was injected into the tumor and ultrasound (frequency 1 MHz, duty 50%, burst rate 2 Hz, intensity 0–4 W/cm²) was transdermally applied to the tumor for 2 min via ultrasonic gel. The anti-tumor effects were evaluated by measuring tumor volume using the formula: (major axis cm²) × (minor axis cm²) × 0.5.

In vivo depletion assays. The GK1.5 hybridoma (rat anti-mouse CD4 mAb) and 53-6.72 hybridoma (rat anti-mouse CD8 mAb) were purchased from the American Type Culture Collection (Manassas, VA, USA). BALB/c nude mice were injected i.p. with each hybridoma, and the ascites were collected to purify antibodies by protein A column (GE Healthcare Japan, Tokyo, Japan). On day 8 after inoculation of Colon-26 tumor cells, mice were intratumorally injected with BL or saline, followed by ultrasound (frequency 1 MHz, duty 50%, burst rate 2 Hz, intensity 4 W/cm²). In addition, mice received 2 i.p. injections (days 5 and 12) of 100 μL/mouse anti-mouse CD8 antibody (CD8⁺ cells) or anti-mouse CD4
antibody (CD4+ cells). Other mice received 5 i.p. injections of 200 µL/mouse anti-asialoGM1 mAb (Wako Pure Chemical Industries) (NK cells) on days 5, 6, 7, 8 and 13. Other mice received isotype IgG (normal rat IgG) as a control for antibody injection. Tumor volume was measured on similar days after ultrasound.

Statistical analysis. All animal groups contained four to six mice. The data are expressed as mean ± SD. The different groups were compared with non-repeated measures ANOVA and Dunnett’s test. Statistical significance was set at P < 0.05.

Results

Heat generation in tumor tissue with Bubble liposomes and ultrasound. In vivo studies were conducted with BALB/c mice to test the impact of BL collapse on heat generation in the tumor during ultrasound exposure. Ten days after subcutaneous inoculation of Colon 26 tumor cells, the anesthetized animals were intratumorally injected with BL or saline, followed by ultrasound exposure. Figure 1a shows that tumor temperature gradually increased with ultrasound intensity. In contrast, tumor temperatures were significantly higher in the presence of intratumoral BL, and the overheating effect increased with ultrasound intensity. In the treatment of BL and 4 W/cm² ultrasound exposures, the tumor temperature gradually increased and achieved the plateau at approximately 1.5 min. Finally, this tumor temperature at 2 min with BL + ultrasound was 6°C higher than with saline + ultrasound (Fig. 1b).

Impact of Bubble liposomes ultrasound-mediated tumor damage. Studies were conducted with BALB/c mice to test the impact of BL on tumor damage. Eight days after subcutaneous inoculation of Colon-26 tumor cells, the anesthetized animals were intratumorally injected with BL or saline, followed by ultrasound exposure. Histopathological changes were assessed by H&E staining (Fig. 2). The tumors were not affected by the 2-min ultrasound exposure, regardless of ultrasound intensity. In contrast, the presence of intratumoral BL caused tissue necrosis starting at 3 W/cm², and even more necrosis at 4 W/cm².

Bubble liposome enhance the anti-tumor effects of ultrasound exposure. The overall anti-tumor effect of ultrasound exposure was determined for 22 days after BALB/c mice were inoculated with Colon-26 tumor cells. The animals were exposed to ultrasound or a combination of BL and ultrasound on day 8 after inoculation. We first examined an anti-tumor effect with ultrasound alone. There was a tendency toward tumor growth suppression at 1–3 W/cm², and a weak anti-tumor effect with 4 W/cm² (P < 0.05; Fig. 3a), suppressing tumor growth to approximately 70% of the control, a reduction of 30% (Fig. 3c). Second, we examined an effect of intratumoral injection of BL. In the presence of intratumoral BL, significant anti-tumor responses were detected, starting with 2 W/cm², and increasing with ultrasound intensity (P < 0.05 and 0.01; Fig. 3b). At an intensity of 4 W/cm², the combination of BL and ultrasound suppressed tumor growth by approximately 45% compared with control (non-treatment) animals (Fig. 3d). We also examined the anti-tumor effect by intratumoral BL injection without ultrasound exposure in another experiment. On day 21 after intratumoral BL injection, tumor volume (%) was 109.2 ± 23.8 (mean ± SD, n = 5) compared to non-treatment mice, indicating no tumor growth suppression without ultrasound.

The results in Figure 3a and b are from independent experiments. Tumor volume was measured on similar days after tumor inoculation, but resulted in different tumor volumes. To compare the anti-tumor effects between these experiments, the tumor volumes represented in Figure 3c and d were normalized to control tumors from each experiment.

Immune cells responsible for tumor growth suppression by Bubble liposomes + ultrasound exposure. The combination of BL and ultrasound damaged tumors, suggesting that tumor-associated antigens could be released from the damaged cells and activate immune cells responsible for tumor growth suppression. Therefore, we investigated the involve-
ment of immune cells known to play major roles in anti-tumor cellular immunity: CD4+ T cells, CD8+ T cells and NK cells (Fig. 4). Depletion of NK cells or CD4+ T cells did not attenuate the anti-tumor effect of BL + ultrasound exposure. In contrast, the depletion of CD8+ T cells, or CD4+ and CD8+ T cells, effectively blocked the anti-tumor effect of BL + ultrasound. These experiments demonstrate that CD8+ T cells were the predominant effector cells in this therapeutic response.

Discussion
Nanobubble collapse in ultrasound fields (i.e. acoustic cavitation) is an extremely rapid process. This phenomenon leads to
localized heating of the bubble interior, which breaks molecular bonds of the gas and vapor. The heat generation has the potential to induce necrosis. Therefore, bubble collapse could be an asset for ablative cancer therapies. The present study demonstrates that the injection of BL into the tumor considerably improves the anti-tumor capacity of ultrasound exposure.

First, in vivo experiments showed higher tumor temperatures after treatment with a combination of BL and ultrasound than with ultrasound alone and the benefit increased with beam intensity (Fig. 1). Morris et al. report additional temperature rise because of friction between the thermocouple and the biological tissue upon ultrasound exposure. In that experiment, a HIFU system was utilized and the ultrasound intensity was monitored. Each point represents the mean ± SD (n = 5, 6).

The applicability of BL and ultrasound exposure to cancer therapy was tested with regard to the tumor growth rate (Fig. 3). Ultrasound only suppressed tumor growth at the highest intensity of 4 W/cm². The mechanism of this tumor growth suppression is not clear. As shown in Figure 1, temperature in tumor gradually increased with increasing ultrasound intensity also upon treatment with ultrasound exposure alone. Therefore, some tumor cells may be damaged. The combination of BL and ultrasound effectively caused tumor growth suppression starting at 2 W/cm². With BL present, an effect on the tumor growth could be seen at lower ultrasound intensities than without BL and at the same ultrasound intensity a larger effect was achieved with BL. We recently reported that BL can be used for gene delivery under low intensity ultrasound (<1 W/cm²), without cytotoxicity. Therefore, low-intensity ultrasound would be preferable for safe gene delivery by BL, whereas higher intensities (2–4 W/cm²) would be more efficient in combination with the combination of BL and ultrasound in cancer therapy. An additional parameter to consider for the anti-tumor effect is BL concentration. We have not optimized the concentration of BL yet; however, we think that there is an optimal concentration, as in gene delivery, for the combination of BL and ultrasound. At too high a concentration, the BL attenuated the ultrasound beam, which resulted in insufficient cavitation being induced for effective gene delivery. In short, higher concentration of BL disturbs the ultrasound transmission and results in it not being effective in inducing cavitation. Finally, tumor tissue would not be effectively insured under this condition; we should optimize the concentration of BL.

The mechanism of tumor growth suppression was investigated by in vivo cell depletion assay because the immune system was implicated in tumor regression during radiation therapy. Local radiation stimulated the production of tumor peptide-reactive IFNγ-producing antitumor immune cells and their trafficking to tumor-draining lymph nodes and tumors. In addition, clinical studies conducted with cancer patients reported that HIFU tumor ablation induces the infiltration of various lymphocyte subsets, including CD4+ and CD8+ T cells, as well as NK cells. The combination of BL and ultrasound exposure might induce damage to tumor cells by making pores in cell membrane with mechanical effects such as induction of jet stream associated with cavitation of BL and by thermal effect. Therefore, we hypothesized that this combination of BL and ultrasound exposure may also induce the release of tumor-associated antigens via the pores of the damaged cells that could prime the antitumor immune system. CD8+ T cell depletion and the combination of CD4+ and CD8+ T cell depletion completely inhibited BL + ultrasound-mediated tumor growth suppression (Fig. 4). For these treatment groups, tumor growth was rather enhanced. The reason for the increased tumor growth was most likely suppression of the immune system, in a similar way as seen with immunosuppressive agents. In CD4+ and CD8+ T cells depleted mice, tumor growth was faster than in non-treated mice, indicating that T cell depletion accelerated tumor growth. In another report, the same phenomenon was observed. In contrast, neither CD4+ T cells nor NK cell depletion dramatically inhibited tumor growth suppression. These data are consistent with the essential role
ascribed to CD8+ T cells in radiation-mediated tumor growth regression. Furthermore, we showed that this immune response was subset-specific because CD4+ T cells and NK cells were not involved in the anti-cancer effect. Altogether, these data show that the anti-tumor effect in BL + ultrasound therapy specifically involves CD8+ T cells.

In our combination therapy of BL + ultrasound, tumor tissue was partially destroyed (Fig. 2). Under this condition, tumor tissue might leak from the primary tissue into the blood flow and induce metastasis. However, in our case, cellular immune system, especially CD8+ T cells, has been induced against cancer cells. Therefore, we expect that this immune system would suppress tumor metastasis. HIFU treatment also destroys tumor tissue and might increase the risk of tumor metastasis due to leaking of tumor cells into the blood flow. However, Xing et al. reported that the HIFU treatment did not increase the risk of distant metastasis.\(^{34}\) They reported the induction of an anti-tumor immune response that may be harnessed to improve the overall effectiveness and quality of cancer therapy. Previously, we also reported that induction of the cellular immune system was very important to suppress tumor metastasis.\(^{35}\) Therefore, we believe that an induction of immune response is a significant benefit in ultrasound therapy.

In conclusion, the present study suggests that injection of BL in combination with low intensity ultrasound may be an effective cancer therapy. We provide evidence that these conditions stimulate the anti-tumor immune responses necessary for tumor growth regression.

Acknowledgments

We are grateful to Dr Yasuhiro Matsumura and Dr Masahiro Yasunaga (Investigative Treatment Division, Research Center for Innovative Oncology, National Cancer Center Hospital East, Japan) for their technical advices on cancer therapy, to Ms. Kyoko Hobo and Ms Yukika Koizumi (Laboratory of Drug and Gene Delivery System, Faculty of Pharma-Sciences, Teikyo University, Japan) for their technical assistance, and to Mr Yasuhiyo Hayakawa and Mr Koشو Suzuki (Nepa Gene, Chiba, Japan) for their technical advice on ultrasound exposure. The authors would like to thank Ms. Lindsey Brinton (Department of Biomedical Engineering, University of Virginia) and Dr. Siva Sai Krishna Dasa (Robert M. Berne Cardiovascular Research Center, University of Virginia) for the English language review.
