Crystal engineering of a family of hybrid ultramicroporous materials based upon interpenetration and dichromate linkers†

Hayley S. Scott,‡a Naoki Ogiwara,‡b Kai-Jie Chen,‡a David G. Madden,‡a Tony Pham,‡b Katherine Forrest,a Brian Space,c Satoshi Horike,b John J. Perry IV,a Susumu Kitagawa*bd and Michael J. Zaworotko*a

A new family of 2-fold interpenetrated primitive cubic (pcu) networks of formula [M(L)2(Cr2O7)]n (M = Co2+, Ni2+, Cu2+ and Zn2+; L = 4,4′-azopyridine), DICRO-3-M-i, has been synthesised and their structures, permanent porosity and gas sorption properties were comprehensively characterised. Molecular simulations indicate that CO2 molecules occupy both of the two distinct ultramicropores that run through this isostructural series. The orientation of the Cr2O72− pillars is thought to contribute to high isosteric enthalpy of adsorption (Qst) towards CO2 and temperature programmed desorption experiments reveal that DICRO-3-Ni-i selectively adsorbs CO2 from gas mixtures that simulate flue gas. Performance in this context is among the highest for physisorbents measured to date and these materials are readily regenerated at 50 °C.

Introduction

Crystal engineering1 exploits structural information at the molecular level to design new crystal structures and, in turn, assert control over physicochemical properties. To date, crystal engineering has evolved to the point that it offers rational design strategies for the synthesis of new families of crystalline materials that can afford control over important functional properties such as porosity, chirality and solubility. With respect to porosity, the “node-and-linker” strategy2 has enabled the rapid development of porous Metal–Organic Materials (MOFs),3 including coordination networks known as porous coordination polymers (PCPs)4 and/or metal–organic frameworks (MOFs).5

We have recently undertaken systematic examination of an underexplored subclass of porous materials that combines two key features, which together can enhance selectivity towards certain sorbates and stability towards humidity: incorporation of strong electrostatics thanks to the use of inorganic linker anions that expose electronegative atoms to pore walls; the use of short organic linker ligands or interpenetration to generate ultramicropores (<0.7 nm). The resulting materials, Hybrid Ultramicroporous Materials, HUMs,6,7 can exhibit strong and selective adsorption sites for important sorbates such as CO2. Indeed, HUMs have set a series of benchmarks for selectivity (S) to CO2 over competing less polarisable gases like N2 (S(N2)) and vapours such as H2O (S(H2O)).6b

An important feature of HUMs is that they are inherently modular, which makes them amenable to fine-tuning through substitution of one or more of their components. To date, we have developed two related platforms of HUMs using the same simple design strategy, i.e. the use of inorganic linker anions to

Scheme 1 Self-assembly of pillared pcu topology networks from sql networks cross-linked by linear inorganic anions that serve as pillars.

† Electronic supplementary information (ESI) available: PXRD, TGA, FT-IR, molecular simulations, structural and sorption data. CCDC 1468766-1468769. For ESI and crystallographic data in CIF or other electronic format see DOI: 10.1039/c6sc01385f
‡ H. S. S. and N. O. contributed equally.

pillar square grid lattice (sq) coordination networks (Scheme 1). The resulting networks are based upon the following linker anions: hexafluorometallate anions (e.g. SiF$_6^{2-}$, SIFSIX$^-$) that pillar in linear fashion to generate primitive cubic (pcu) networks.$^8$ This platform also includes analogues which exhibit supermicropores, i.e. >0.7 but <2 nm); a mmo topology networks that incorporate angular pillars which enable self-penetration of the sq nets (CrO$_6^{2-}$, MoO$_4^{2-}$, WO$_4^{2-}$).$^9$ We have also reported the first porous pcu network sustained by Cr$_3$O$_6^{3-}$ (DICRO) linear linkers, DICRO-2-Ni-4$^+$ (2 = 1,2-bis(4-pyridyl) acetylene), but a hitherto unprecedented angled mode of interpenetration mitigated against strong gas sorption performance towards CO$_2$.$^*$ The first two platforms seem to validate the effect upon gas sorption performance when combining ultramicropores and high electrostatics in the same material. Specifically, their modular nature enabled systematic fine-tuning of both pore size and pore chemistry to optimise physiosorption performance. These observations prompted us to study other families of HUMs.

Two crystal engineering approaches exist for the formation of networks that exhibit ultramicropores: incorporation of short linkers (<0.7 nm); interpenetration of two or more networks of networks that exhibit ultramicropores and high electrostatics in the same material. Specifically, their modular nature enabled systematic fine-tuning of both pore size and pore chemistry to optimise physiosorption performance. These observations prompted us to study other families of HUMs.

We report herein a family of 2-fold interpenetrated HUMs based upon DICRO pillars: $[M(4,4'-azopyridine)$_2(Cr$_2$O$_7$)$_2]_n$, DICRO-3-M-i, (3 = 4,4'-azopyridine; $M$ = Co$^{2+}$, Ni$^{2+}$, Cu$^{2+}$, Zn$^{2+}$). DICRO-3-M-i form pcu topology networks which exhibit offset interpenetration and their pore walls are lined by inorganic moieties, unlike DICRO-2-Ni-4$^+$. The DICRO-3-M-i family was characterised by single-crystal and powder X-ray diffraction, thermogravimetric analysis (TGA), FT-IR spectroscopy (FTIR), single component gas sorption measurements (CO$_2$ and N$_2$), molecular simulations of CO$_2$ adsorption, and temperature programmed desorption (TPD) experiments coupled with TGA/mass spectrometry (MS). We evaluated the performance of DICRO-3-Ni-i in the context of direct capture of CO$_2$ from air and five other gas mixtures including simulated flue gas. The stability of DICRO-3-Ni-i to atmospheric water vapour was studied via standard accelerated stability tests$^*$ that simulate long-term storage or “shelf-life”.

Results and discussion

Syntheses and characterisation

Single-crystals of DICRO-3-M-i ($M$ = Ni$^{2+}$, Cu$^{2+}$, Zn$^{2+}$) were prepared via slow diffusion of aqueous $K_2Cr_2$O$_7$/$M(NO_3)_2$ into MeCN solutions of ligand 3 at room temperature. Yellow block-shaped crystals were obtained after one week. Single-crystals of DICRO-3-Co-i were synthesised by heating a sealed vial of reagents dissolved in H$_2$O to 120 °C for 48 h, followed by cooling to 30 °C over 6 h. DICRO-3-Co-i formed as small, block-shaped, dark red coloured crystals that were weakly diffracting. As such, the crystallographic data for DICRO-3-Co-i is of low quality; however, the space group and crystal packing matches the other three compounds in the series. DICRO-3-M-i were also synthesised via direct mixing of reagents to afford powder samples suitable for use in gas sorption studies. All four compounds were found to be stable after one week of exposure to ambient conditions. PXRD data are provided in the ESI; Fig. S1–S4.$^+$ Thermogravimetric analyses reveal that all four compounds exhibit thermal stability to a least 200 °C (Fig. S5$^+$). Infrared spectra are presented in Fig. S6.$^+$

**Structural analysis**

Single-crystal diffraction analysis of DICRO-3-M-i revealed that they are isostructural, crystallising in the triclinic space group P1. The hexacoordinate metal centres serve as six-connected (6-c) nodes in pcu topology networks.$^+$ Four pyridyl groups from four different linker ligands comprise the equatorial plane (Fig. 1) which propagates to the expected sq nets. Average M$^{2+}$–N bond lengths, 2.15 Å (Co), 2.08 Å (Ni), 2.02 Å (Cu) and 2.16 Å (Zn), are consistent with the DICRO-1-M-i family according to data archived in the Cambridge Structural Database (CSD).$^3$ The axial positions of the M$^{2+}$ centres coordinate to oxygen atoms from Cr$_2$O$_7^{2-}$ anions, which pillar the sq nets to afford the observed pcu networks. A survey of the CSD revealed that, excluding polyoxometalates, there are only 23 structures of transition metals coordinated to Cr$_2$O$_7^{2-}$ anions. Of these, 18 structures involve Cr$_2$O$_7^{2-}$ ligands that are bridging. M$^{2+}$–O distances of 2.012(7) Å (Co), 2.047(3) Å (Ni), 2.274(4) Å (Cu) and 2.088(2) Å (Zn) are within expected ranges. The Cu–O bonds in DICRO-3-Cu-i are elongated because of Jahn–Teller distortion. Cr ions exhibit tetrahedral geometry with average O–Cr–O angles of 109.65(4)$^*$ (Co), 109.20(17)$^*$ (Ni), 108.2(2)$^*$ (Cu) and 109.24(12)$^*$ (Zn). In each compound, the terminal Cr–O bond distances are shorter than the bridging Cr–
The interpenetrated mode of interpenetration is commonly encountered in 2-fold interpenetration in which the node of the second net is "offset" from the cavity of the first net (Fig. 2). This mode of interpenetration is commonly encountered in 2-fold interpenetrated \textit{pcu} networks and is also seen in \textit{DICRO-1-M-i}.\textsuperscript{11-13} The offset arrangement could be an artifact of C-H⋯O interactions between pyridyl groups of one network and the \textit{DICRO-3-}\textit{i} network of the adjacent network (Fig. S7–S8\textsuperscript{†}).

Notably, offset interpenetration results in four crystallographically distinct channels running through the structure parallel to the \(a\)-axis. However, only two of these channels are large enough to accommodate even small guest molecules. Channels A and B (Fig. 2) exhibit pore diameters of 4.4–5.8 Å and 3.0–3.4 Å, respectively, based upon the closest O⋯O and C⋯C distances for channels A and B respectively (minus van der Waals radii). The larger of the two channels is lined by terminal O-atoms from \(\text{Cr}_2\text{O}_7^{2-}\) pillars (O6) that orient towards the inside of the channel. For channel B, the terminal O-atom (O3) does not protrude into the cavity. The location of accessible O-atoms from the dichromate inorganic pillars in these networks could be of significance with respect to gas sorption, as discussed earlier and below. Channel A has features that resemble a member of the \textit{MFSIX} platform, \([\text{Cu(L)}_2(\text{SiF}_6)]\) \(\text{(L} = 1,2\text{-bis(4-pyridyl)acetylene)}\), \textit{SIFSIX-2-Cu-i},\textsuperscript{78} which displays centred, 2-fold interpenetration and one type of channel. This is because the staggered disposition of the interpenetrated nets results in electronegative atoms (O-atoms in the case of \textit{DICRO}, F-atoms in the case of \textit{SIFSIX}) protruding into the channel walls in such a manner that the electronegative atoms are 7–8 Å apart. These features are discussed in relation to gas sorption and isosteric enthalpy of adsorption in the next section.

\textbf{Gas sorption analyses}

Single component \(\text{CO}_2\) and \(\text{N}_2\) sorption measurements were performed on \textit{DICRO-3-Ni-i}, \textit{DICRO-3-Co-i} and \textit{DICRO-3-Cu-i} to determine gas uptake, ideal selectivity and isosteric enthalpy of adsorption (\(Q_{st}\)). PXRD patterns reveal that \textit{DICRO-3-Zn-i} loses crystallinity with loss of solvent and it also exhibits low uptake of \(\text{N}_2\) at 77 K and \(\text{CO}_2\) at 195 K (Fig. S9 and S10\textsuperscript{†}). \textit{DICRO-3-Zn-i} was therefore not studied further in terms of gas sorption. The permanent porosities of \textit{DICRO-3-Co-i}, \textit{DICRO-3-Ni-i} and \textit{DICRO-3-Cu-i} were established by \(\text{N}_2\) isotherms at 77 K (Fig. S9\textsuperscript{†}). The apparent BET surface area was calculated to be 142, 388 and 325 m\(^2\) g\(^{-1}\) for \textit{DICRO-3-Co-i}, \textit{DICRO-3-Ni-i} and \textit{DICRO-3-Cu-i}, respectively. Pore volumes of 0.052, 0.143 and 0.122 cm\(^3\) g\(^{-1}\) for \textit{DICRO-3-Co-i}, \textit{DICRO-3-Ni-i} and \textit{DICRO-3-Cu-i} were calculated by assuming liquid filling of \(\text{N}_2\) at the \(P/\text{P}_0\) = 0.95. These values are similar to those calculated from the

crystallographic data using PLATON\textsuperscript{16} for DICRO-3-Ni-i and DICRO-3-Cu-i (0.158 and 0.151 cm\textsuperscript{3} g\textsuperscript{-1}, respectively). The lower uptake exhibited by DICRO-3-Co-i could be attributed to partial collapse of the network following activation.

CO\textsubscript{2} and N\textsubscript{2} sorption isotherms at 273, 283 and 293 K were collected for DICRO-3-Co-i, DICRO-3-Ni-i and DICRO-3-Cu-i. 293 K isotherms for both gases are presented in Fig. 3 (top), while 273, 283 and 293 K isotherms are given in the ESI (Fig. S11–S13). A summary of gas sorption data is also provided in Table 2. DICRO-3-Co-i and DICRO-3-Ni-i both exhibit type I isotherms for CO\textsubscript{2} sorption whereas DICRO-3-Cu-i has a distinct step and hysteresis. The step observed in the CO\textsubscript{2} adsorption isotherms for DICRO-3-Cu-i varies with temperature, occurring at higher partial pressures and becoming more gradual at higher temperature. The stepped nature of the isotherm observed for DICRO-3-Cu-i may be due to either of two structural changes: translation of independent networks with respect to one another upon increased CO\textsubscript{2} sorption, a phenomenon that has been reported previously for similar systems;\textsuperscript{37} flexible networks switching between a narrow pore (NP) and a large pore (LP) form, which has also been observed in peu networks.\textsuperscript{17,18}

Since, stepped isotherms were not observed for the Cu, Ni and Zn analogues it seems unlikely that translation of independent networks is the origin for the stepped behaviour seen in DICRO-3-Cu-i. Cu\textsuperscript{2+} exhibits Jahn–Teller distortion, which is known to be temperature dependent (the distortion is less pronounced at higher temperatures). The stepped nature of the isotherm could therefore be a consequence of the effect of Jahn–Teller distortion upon the coordination sphere, which would in turn affect the pore size and shape. To verify this hypothesis, PXRD experiments were conducted on ‘as-synthesised’ powder at ambient pressure, at reduced pressure and again after the powder was cycled back to ambient pressure. A phase change is apparent from the PXRD patterns (Fig. S14\textsuperscript{f}) but attempts to collect diffraction data on single-crystals of DICRO-3-Cu-i at reduced pressure were unsuccessful.

Selectivity for CO\textsubscript{2} over N\textsubscript{2} \(S_{\text{CN}}\) for DICRO-3-Co-i, DICRO-3-Ni-i and DICRO-3-Cu-i was calculated from the uptakes of CO\textsubscript{2} at 0.15 bar and N\textsubscript{2} at 0.85 bar at 293 K to be 70.2, 79.3 and 145.9, respectively. The relatively high \(S_{\text{CN}}\) for DICRO-3-Cu-i is partly a result of its very low N\textsubscript{2} uptake at 293 K. Such \(S_{\text{CN}}\) values are comparable to porous MOMs containing amino-functional groups and open-metal sites, which are absent herein.\textsuperscript{19}

CO\textsubscript{2} isotherms measured at 273, 283 and 293 K were fitted using the virial equation (Fig. S15, S17, S19f), and the isosteric enthalpy of adsorption \(Q_{\Gamma}\) was calculated using the Clausius–Clapeyron equation.\textsuperscript{20} \(Q_{\Gamma}\) values at low loading for DICRO-3-Co-i, DICRO-3-Ni-i and DICRO-3-Cu-i are 35, 37 and 37 KJ mol\textsuperscript{-1}, respectively (Fig. S16, S18, S20f). The relatively flat shape of the \(Q_{\Gamma}\) curves indicates that the binding energy is relatively independent of loading. As mentioned earlier, SIF-SIX-2-Cu-i exhibits similar pore size, shape and chemistry to channel A of the DICRO-3-M-i family. \(Q_{\Gamma}\) values at mid-loading (SIF-SIX-2-Cu-i = 35 KJ mol\textsuperscript{-1}; DICRO-3-Cu-i = 35 KJ mol\textsuperscript{-1}) and curve shapes are indeed comparable. \(Q_{\Gamma}\) values for DICRO-3-M-i are also similar or higher than seen for MOF-5 (34 KJ mol\textsuperscript{-1}),\textsuperscript{41} HKUST-1 (35 KJ mol\textsuperscript{-1}),\textsuperscript{22} MAF-25 (26 KJ mol\textsuperscript{-1}),\textsuperscript{23} InOF-1 (29 KJ mol\textsuperscript{-1})\textsuperscript{44} and NOTT-140 (25 KJ mol\textsuperscript{-1}).\textsuperscript{22} However HUMs with mmo topology exhibit narrower pores and much higher \(Q_{\Gamma}\) values at low loading: MOFOUR-1-Ni (56 KJ mol\textsuperscript{-1}),\textsuperscript{46} CROFOUR-1-Ni (50 KJ mol\textsuperscript{-1})\textsuperscript{46} and WOFOUR-1-Ni (65 KJ mol\textsuperscript{-1}).\textsuperscript{46} Comparison can also be made with DICRO-2-Ni-i, for which the pore diameter (3.6 Å) is intermediate to those of channels A and B of DICRO-3-M-i. The Cr\textsubscript{2}O\textsubscript{2}\textsuperscript{−} pillar is directed away from the accessible channel in DICRO-2-Ni-i but towards the interior of the channel in DICRO-3-M-i. The larger \(Q_{\Gamma}\) values of DICRO-3-M-i vs. DICRO-2-Ni-i (30.5 KJ mol\textsuperscript{-1})\textsuperscript{46} support the importance of pore size and pore chemistry seen for the MFSIX platform.\textsuperscript{78} While interpenetration necessarily reduces pore dimensions, likely enhancing binding interactions between sorbate and sorbent, interpenetration may also afford non-uniform pores and significantly change pore structure. Whereas uniform pore binding is likely to be generally preferred for enhanced selectivity, different sorbates could require very different pore structures to optimise the energetics of binding. Therefore, generalisation about the influence of interpenetration upon separations is inappropriate since interpenetrated networks may in some circumstances be more able to create uniform pores than their non-interpenetrated analogues.
Molecular simulations

Molecular simulations of CO₂ adsorption for DICRO-3-Ni-i and DICRO-3-Cu-i indicate that guest CO₂ molecules are adsorbed into both channels A and B and that, at CO₂ saturation, CO₂ molecules interact with exposed oxygen atoms of the Cr₆O₇²⁻ pillar (Fig. 4). The tight fit within the channels and the presence of exposed oxygen atoms from Cr₆O₇²⁻ pillars, contributes to the relatively high zero loading CO₂ Qₘ values for these HUMs. Simulations of CO₂ adsorption at 273, 283 and 293 K were performed for DICRO-3-Ni-i and DICRO-3-Cu-i. For DICRO-3-Ni-i isotherms are in good agreement with the experimental data (Fig. S21†). However, for DICRO-3-Cu-i simulated CO₂ isotherms correspond well with experimental data only in the low and high-pressure regions of the isotherms for the three temperatures, i.e., before and after the inflection point in the experimental isotherms (Fig. S22†). The simulated Qₘ values are also in good agreement with experiment at 32.8 (vs. 37) and 33.5 kJ mol⁻¹ (vs. 37) for DICRO-3-Ni-i and DICRO-3-Cu-i, respectively (Fig. S23, S24†). The simulations for DICRO-3-Cu-i do not show the inflection point from the experimental CO₂ isotherms because the HUM is treated as a rigid network in the simulations. The simulations indicate that the X-ray crystal structure for DICRO-3-Cu-i is representative of the structure occurring after the step (at higher pressure) in the experimental isotherms.

Accelerated stability and temperature programmed desorption

Because of its relatively high CO₂ uptake and Qₘ, DICRO-3-Ni-i was selected for testing regarding its stability and ability to uptake CO₂ directly from the atmosphere, as well as under simulated flue gas conditions. The stability of DICRO-3-Ni-i to atmospheric water vapour was evaluated via accelerated stability testing,⁶⁸ which simulates long-term storage and shelf-life (see ESI for full details and Fig S27–S29†). The surface area of DICRO-3-Ni-i was found to decrease upon increased exposure. An as-synthesised sample exhibited a BET surface area of 388 m² g⁻¹, while surface areas for 1 day, 7 days and 16 days were 289 m² g⁻¹ (−25%), 255 m² g⁻¹ (−34%) and 173 m² g⁻¹ (−55%), respectively. The stability of DICRO-3-Ni-i is comparable to HKUST-1 (−28% surface area following 1 day exposure; −33% after 7 days) but superior to Mg-MOF-74 (−74% surface area following 1 day exposure).⁶⁸ The performance of DICRO-3-Ni-i for capturing CO₂ directly from air and under conditions resembling flue gas streams was also evaluated. TGA/MS was used to determine quantitative uptakes of specific adsorbents from these gas streams (full details given in ESI). DAC measurements on DICRO-3-Ni-i revealed a CO₂ uptake of −0.97 L CO₂ per kg (−2 mg CO₂ per g solid) when exposed to the laboratory atmosphere for 12 h (see Fig. S30† for schematic diagram of DAC/TPD apparatus; all TPD and uptake plots are located in Fig. S32–S40 and data tabulated in Table S9†). This equates to a Scw CO₂ : H₂O ratio of >2% : <97% in terms of mass uptake for each component, which is above that measured for HKUST-1 (1% : 99%) but lower than that of SIFSIX-3-Ni (8% : 92%) and Mg-MOF-74 (4% : 96%).⁶⁸ Under simulated flue gas conditions (moist CO₂, 0.15 atm), DICRO-3-Ni-i exhibits high uptake of CO₂, ~9.77 L CO₂ per kg (19.2 mg CO₂ per g solid) (Fig. 5). This equates to a Scw CO₂ : H₂O ratio of 53% : 47% which is higher than that of HKUST-1 (8.5% : >91%), slightly higher than that of Mg-MOF-74 (51% : 49%) and second only to SIFSIX-3-Ni (62% : 38%) when tested under the

same conditions. TPD experiments revealed that desorption occurs below 50 °C for DICRO-3-Ni-i, which is relatively easier than both HKUST-1 and Mg-MOF-74.

Conclusions

A family of 3D Hybrid Ultramicroporous Materials (HUMs), DICRO-3-M-i, with four members has been synthesised using a crystal engineering approach that exploits Cr₂O₇²⁻ anions to pillar square lattice networks (sql) constructed from 4,4'-azo-pyridine organic linkers (3) and M²⁺ metal centres. Single component gas sorption measurements for three of these compounds, DICRO-3-Co-i, DICRO-3-Ni-i and DICRO-3-Cu-i, were collected and reveal permanent microporosity, selective CO₂/N₂ uptake and relatively high Qₛ values towards CO₂. Temperature programmed desorption experiments conducted on DICRO-3-Ni-i revealed excellent CO₂ uptake and SₛCN when exposed to flue gas conditions. Structural analysis, gas sorption experiments and molecular simulations from this study reafﬁrm that HUMs can afford favourable sorbate–sorbent interactions. Specifically, for the DICRO-3-M-i family, Cr₂O₇²⁻ anions orient in such a manner that terminal O-atoms line the walls of the accessible 1D ultramicroporous channels, resulting in high Qₛ and enhanced CO₂ sorption performance.

To conclude, whereas we have not yet elucidated the origin of the ﬂexibility in this family of materials, there are four take-home messages that could aid the custom-design of porous materials with enhanced gas sorption performance: the combination of ultramicropores and strong electrostatics in HUMs necessarily leads to tight binding sites for polarisable guests such as CO₂; interpenetration can be used to facilitate ultramicropores, but may also generate non-uniform pores; the presence of groups with strong electrostatics alone is not sufficient, but rather these groups must be favourably positioned to achieve optimal guest binding; binding energies of 35–40 kJ mol⁻¹ enable facile regeneration of these sorbents.
