ABSTRACT: We have grown large single crystals of the cluster magnet Nb3Cl8 with a magnetic triangular lattice, and investigated its magnetic properties and crystal structure. In Nb3Cl8, the [Nb3]8+ cluster has a single unpaired spin, making it an S = 1/2 triangular lattice antiferromagnet. At low temperatures, Nb3Cl8 exhibits a magnetic-nonmagnetic phase transition driven by a charge disproportionation, in which the paramagnetic [Nb3]8+ clusters transform into alternating layers of nonmagnetic [Nb3]7+ and [Nb3]9+ clusters. The observed exotic phenomenon with the strong correlation between the magnetism and structure are based on the nature of the cluster magnetism.

INTRODUCTION

Cluster units consisting of several ions are occasionally found in inorganic crystal structures. Clusterization occurs for the gain of electron energy to form a large direct overlap among several ions. “Cluster magnets,” in which each cluster has unpaired electrons similar to a radical ion, are classified as localized spin systems. Such localization is stabilized by a suitable ratio between the transfer integral and the on-site Coulomb repulsion among clusters. When the optimum ratio is hampered, charge fluctuations within a cluster would be enhanced result in an itinerant system. The charge fluctuation properties are among the important characteristics of cluster magnets, but are absent in the ordinal localized spin systems of magnetic ions. As a result, cluster magnets are expected to produce novel phenomena and have been extensively investigated.1-7

Recently, the class of compounds [A]M2X8 (A = interstitial cations, M = transition metal, X = anion) has attracted the attentions of theorists and experimentalists.8-14 As shown in Figure 1(a), the M ions form a “breathing” kagomé network, which consists of two kinds of metal triangles with two distinct metal-metal distances. This deformation of the kagomé lattice produces metal-metal bonding in the short trimers owing to the overlap of their orbitals of d electrons, which results in the formation of a cluster-based triangular lattice. Mo3 cluster compounds typically have the chemical formula [A]M2X8. These clusters often have [Mo3]12- and [Mo3]10- oxidation states, and are nonmagnetic because of the absence of unpaired spins.9, 15-18 On the other hand, in LiZn2Mo3O8, Li2ScMo3O8, and Li2InMo3O8, since the valence state is [Mo3]11+ with one unpaired spin, each Mo3 cluster shows S = 1/2 magnetism.9,41 Indeed, these compounds show the characteristic phenomena of triangular lattice antiferromagnets: valence bond solid formation observed in LiZn2Mo3O8, spin liquid condensation in Li2ScMo3O8, and magnetic ordering with 120° structure in Li2InMo3O8.9,41

In this study, we have focused on the [A]M2X8 type niobium chloride Nb3Cl8,19,20 in which three Nb ions form a Nb3 trimer resulting in the formation of a Nb3Cl13 cluster unit (Figure 1(b)). Each Nb3 trimer has quite short Nb-Nb intra-cluster distance (dNb-Nb ~ 2.8 Å).20 This fact indicates the formation of metal-metal bondings. In other short Nb-Nb distance compounds, for example, elemental Nb (dNb-Nb = 2.853 Å), LiNbO2 (dNb-Nb = 2.907 Å), NbO2 (dNb-Nb = 2.688 Å), and Nb2F15 (dNb-Nb = 2.799 Å), the formation of the metal-metal bondings has been discussed.21-24 As a result of the metal-metal bondings, the molecular orbitals are formed from three f2g orbitals as depicted in Figure 1(c). Each Nb3 trimer has seven d electrons yielding a valence state of [Nb3]9+. Thus, the [Nb3]9+ clusters would display S = 1/2 magnetism. This electronic state is similar to the above-mentioned [Mo3]11+ systems. On the other hand, Nb3Cl8 exhibits strong lattice instability because the magnetic layers are connected only by weak van der Waals’ forces without binding cations (Figure 1(d)). Therefore, Nb3Cl8 is expected to display different novel phenomena when compared to the other [A]M2X8 systems.

In this paper, we report the investigation of the charge disproportionated magnetic-nonmagnetic phase transition at ~100 K in Nb3Cl8. We discuss the mechanism of the charge disproportionation based on X-ray diffraction, NMR measurements.

EXPERIMENTAL PROCEDURE

Sample Preparation and Characterization Powders of NbCl3 and elemental Nb were used as starting materials. For the synthesis of the precursor, a mixture of the starting materials with the molar ratio Nb:Cl = 3:8 was calcined in a sealed silica tube under an Ar atmosphere at 700°C for 48h. Single crystals of Nb3Cl8 were grown at 750°C for 150h from the precursor powders by the solvent evaporation PbCl2 flux
method. After the growth was complete, the remaining PbCl$_2$ was removed by soaking the crystals in hot water. Powder samples of Nb$_3$Cl$_8$ were prepared by sonicating the obtained single crystals, in order to prevent chemical decomposition by the mechanical grinding. The SEM images, obtained by using a SEM/EDS spectrometer (SU1510, HITACHI), reveal that the powder samples consist of a conglomerate of thin nanoscale single crystals (see Figure. S2 in Supporting Information). The samples were characterized by powder X-ray diffraction (XRD) on a diffractometer using Cu Ka radiation.

**Measurement of Physical Properties**

The temperature dependence of the magnetization was measured under several magnetic fields (up to 7T) by using the magnetic property measurement system (MPMS; Quantum Design) at the LTM Research Center, Kyoto University. $^{93}$Nb-NMR measurements were carried out by the spin-echo technique with a standard phase-coherent-type NMR-pulsed spectrometer. The $^{93}$Nb nucleus with $I = 9/2$ has a nuclear gyromagnetic ratio $\gamma = 10.407$ MHz/T. $^{93}$Nb-NMR spectra were recorded by summation of the fast Fourier transform of spin echo signals at several frequencies in the range 60-65 MHz. Typical pulse lengths were 5 and 10µs for the $\pi/2$- and $\pi$-pulses, respectively, with a pulse separation of $\tau = 150\mu$s.

Single crystal X-ray diffraction experiment were performed with using Rigaku AFC8 diffractometer equipped with a Eulerian 3 circle CCD detector with Mo Ka radiation. Data were collected and processed with solutions and refinements of the crystal structures using the package program of Crystal Clear SM1.3.6 SP3.red (Rigaku/MSC Inc., 2006). A plate-like crystal (0.47 \times 0.45 \times 0.06 mm) was used for single-crystal data analysis. For the low-temperature experiment, a single crystal of Nb$_3$Cl$_8$ was glued with epoxy cement on the tip of a quartz fiber and mounted on a goniometer head.

**RESULTS AND DISCUSSION**

Fine single crystals of Nb$_3$Cl$_8$ were successfully grown. As shown in the inset of Figure 2, the obtained single crystals are dark green hexagonal plates with a typical size of $3 \times 3 \times 0.5$ mm. They are strongly cleavable along the ab-plane similar to black mica, indicating that the magnetic layers are connected by weak van der Waals’ forces. X-ray diffraction patterns (XRD) of the powder and single crystal samples are shown in Figure 2. All peaks of powder sample were indexed to Bragg reflections based on the space group $P3\overline{3}m1$, indicating that a single-phase sample was obtained. The XRD pattern of the single crystal was measured in the condition of the scattering vector parallel to 0 0 l. Only 0 0 l diffractions can be obtained without other diffractions, suggesting a single domain crystal.

Figure 3 shows the temperature dependence of the magnetic susceptibility of single crystal and powder samples Nb$_3$Cl$_8$ ($\chi$ and $\chi_p$). There is a large difference between the $\chi$ and $\chi_p$ curves. At $T \sim 100$ K, $\chi_p$ drops rapidly with a large hysteresis indicating the magnetic phase transition. Below $T^*$, the value of $\chi_p$ approaches to approximately zero, indicating that Nb$_3$Cl$_8$ in the low temperature phase is nonmagnetic. In a low temperature region, $\chi_p$ shows a small Curie tail with sample depending. Such an extrinsic Curie tail is sometimes observed in nonmagnetic compounds including a slight paramagnetic impurity. On the other hand, there is no anomaly at $T^*$ in $\chi_p$, indicating that the phase transition is suppressed in the powder sample. In the high-temperature region, both $\chi$ are well fitted to the Curie-Weiss function.

\[ \chi = \frac{\beta S(S+1)}{kT-\theta_W} \]  
(1)

where $\beta S$ is the effective paramagnetic Bohr magneton and $\theta_W$ is the Weiss temperature as fitting parameters. They are estimated as $\beta S = 1.691(9)$ and $\theta_W = -13.13(3)$ K. The experimentally obtained value of $\beta S$ is consistent with the ideal value of 1.73 for $S = 1/2$, indicating the existence of one unpaired spin on the molecular orbitals of each Nb$_3$ trimer. The negative $\theta_W$ indicates that the magnetic interactions between Nb$_3$ trimers are dominantly antiferromagnetic. The $\chi_p$ curves measured in the parallel and perpendicular fields to the c-axis almost coincide, indicating small magnetic anisotropy in Nb$_3$Cl$_8$.

Powder samples of Nb$_3$Cl$_8$ are in a paramagnetic state down to $T \sim 2$ K. As mentioned in Sec. II A, the powder samples consist of a conglomerate of thin single crystals. In addition, a significant broadening of the 0 0 l XRD peaks is observed in powder samples compared with that of the single crystal as (Figure S3 of Supporting Information). We roughly estimated the average thickness of the crystals in the powder samples using the Scherrer formula $L = K \lambda / \beta \cos \theta$, where $L$ is the average crystallite size, $\lambda$ is the X-ray wavelength, $\beta$ is the peak width of the diffraction peak profile at half maximum (FWHM) in radians, $\theta$ is the Bragg peak position, and $K$ is a constant related to crystallite shape normally taken as 0.9. The estimated average thickness in the powder samples is $L = 0.1022 \mu$m. This value is approximately 28$\mu$m Nb$_3$Cl$_8$ in the low temperature phase of as discussed later. With the reduction in crystal size, stacking faults would be formed simultaneously. As a result, such the decrease of periodicity possibly suppresses the long-range ordering at $T^*$ in the powder samples.

At low temperatures, $\chi_p$ deviates from the Curie-Weiss law, and exhibits a broad peak around 2.5 K suggesting the development of antiferromagnetic correlations. The black solid line in Figure 3 shows the theoretical curve for an $S = 1/2$ Heisenberg triangular lattice antiferromagnet with the interaction $J/k_B = 9.05(2)$ K. The curve is consistent with the observed $\chi_p$. In the framework of the mean-field theory, when there are only nearest-neighbor couplings with the superexchange interaction $J$, $\theta_W$ is given as $-2JS(3S+1)/3k_B$. Thus, $\theta_W = -3/2(J/k_B)$ for the $S = 1/2$ triangular lattice with $z = 6$. The $J/k_B$ value of 8.7(2) K estimated from the Curie-Weiss temperature is close to the value obtained from the fitting using the triangular lattice model.

In order to clarify the microscopic surroundings of Nb ions in the low temperature phase, we measured the $^{93}$Nb-NMR spectra at 78 K by sweeping frequency in a constant external magnetic field of $H = 5.9998$ T applied parallel to the c axis as plotted in Figure 4. When the nuclear spins are in an electric-field gradient (EFG), the NMR spectrum splits due to the nuclear-electric quadrupole interaction. For $^{93}$Nb ($I = 9/2$), the spectrum splits into nine peaks: the central peak ($m = -1/2 \leftrightarrow 1/2$), two first ($m = \pm 1/2 \leftrightarrow \pm 3/2$), two second ($m = \pm 1/2 \leftrightarrow \pm 5/2$), two third ($m = \pm 5/2 \leftrightarrow \pm 7/2$), and two fourth satellite
peaks ($m = \pm 7/2 \cong \pm 9/2$). As shown in the figure, more than 9 peaks are clearly observed. The resonance peaks are interpreted as a superposition of two sets of 9 peaks as shown in the red and blue lines, which suggests the existence of two kinds of Nb sites in the nonmagnetic phase. The fact that the observed peaks have the same approximate interval indicates that the asymmetry parameter $\eta = (V_x - V_y)/V_z$, where $V_{tot}$ is the EFG of $\alpha = x, y, z$ directions, is small. In addition, the similar intensities of both sets suggest that the stoichiometric ratio of two Nb sites is equal in the low temperature phase. TABLE 1 shows the NMR parameters for both Nb sites; the electric-quadrupole frequency $v_0$, the shift from ideal value $K$, and $\eta$. The dominant contribution to the observed shift $K$ is from the chemical shift, since the single crystal NbCl$_6$ is nonmagnetic of NbCl$_8$ layers also changes, that is, double planes are layered on a layer, and the two kinds of the layers are stacked alternately. TABLE 2 shows the NMR parameters for both Nb sites; the electric-quadrupole frequency $v_0$ for Nb1 and Nb2 indicate that the EFGs of the two Nb sites are different, possibly implying differently distorted NbCl$_6$ octahedra.

Figure 5 shows the determined crystal structure for the single crystal NbCl$_6$ at 300 K (left) and 24 K (right) (details are shown in TABLE S1 of Supporting Information). The structure at 300 K is consistent with that of the previous report. We found that the structural phase transition occurred at $T_w$ from $P3m1$ to $R3$ with a $1a \times 1b \times 3c$ supercell in the trigonal structure. Along with the structural phase transition, the stacking pattern of NbCl$_6$ layers also changes, that is, double planes are layered with a shifting of $[1/3, -1/3, 0]$ per unit cell of the high temperature phase (see Figure S1 in Supporting Information). Such the unconventional structural transition could be suppressed by the decrease of structural periodicity in the structure, which is observed in the powder samples. In addition, the stoichiometric ratio of the two Nb sites is equal in the low temperature phase, which is consistent with the result of the NMR investigation. At $T_w$, the uniform Nb$_1$ trimers with the same $d_{Nb-Nb}$ (2.8109(9) Å at 300 K) are divided into two kinds of trimers with different $d_{Nb-Nb}$ ($d_{Nb-Nb}'$ = 2.8013(3)es Å, $d_{Nb-Nb}''$ = 2.8207(17) Å at 24 K). Note that the transformation occurs while maintaining the point group ($C_{3v}$) of the Nb trimers. Each Nb trimer with the same Nb-Nb bond length is arranged on a layer, and the two kinds of the layers are stacked alternately.

**Table 2. Intra-cluster Nb-Nb bond length $d_{Nb-Nb}'$, average Nb-Cl bond length $\langle d_{Nb-Cl}\rangle$, quadratic elongation ($\lambda$), and bond angle variance $\sigma$ for the NbCl$_6$ octahedra in NbCl$_6$ at 300 and 24 K.**

The deviation in the shift of the Nb ions from the center of NbCl$_6$ octahedra results in different degrees of distortion in each NbCl$_6$ octahedron. As a scale-parameter of distortion of octahedra, we introduce two parameters. The quadratic elongation is defined as,

$$\lambda = \sum_{i=1}^{n} \frac{l_i/l_0}{n},$$

where $n$ is the coordination-number of anions around the central cation, $l_i$ is the bond length between the central cation and the $i$-th coordinating anions, and $l_0$ is the bond length in a polycrystal with $O_h$ symmetry whose volume is equal to that of the distorted one. The bond angle variance is expressed as,

$$\sigma = \sqrt{\frac{\sum_{i=1}^{n} \phi_i^2 - \phi_0^2}{n-1}},$$

where $m$ is the number of anion-cation-anion bond angles, $\phi_i$ is the $i$-th bond angle of the distorted coronation-polyhedra, and $\phi_0$ is the bond angle of the coordination-polyhedra with $O_h$ symmetry. The parameters ($\lambda$) and $\sigma$ represent the deviation of each bond length of Nb-C1 and bond angle of CI-Nb-C1, respectively. Using these parameters, the degree of the deviation in the NbCl$_6$ octahedra can be evaluated. TABLE 2 shows the estimated ($\lambda$) and $\sigma$ for each NbCl$_6$ octahedra in the high and low-temperature phases. The values of both parameters in the shrunk Nb1 trimers increase, while the values in the expanded Nb2 trimers decrease. The ($\lambda$) and $\sigma$ values directly relate to EFG. Thus, the different ($\lambda$) and $\sigma$ values for the Nb1 and Nb2 sites are consistent with the $^{93}$Nb-NMR results. The phase transition accompanied by the expansion and shrinking of the Nb$_1$ trimers at $T_w$ can be explained by the charge disproportionation model as schematically described in Figure 6. In the high-temperature phase, the valence state of the uniform Nb$_1$ trimers is $[Nb]^+$ with seven $4d$ electrons. In this state, each Nb$_1$ trimers exhibits $S = 1/2$ magnetism. However, when the Nb$_1$ trimers undergo charge disproportionation into $[Nb]^3+$ and $[Nb]^+$, they become nonmagnetic due to the absence of unpaired spins. In this way, the observed magnetic-nonmagnetic phase transition at $T_w$ could be described by $[Nb]^+$ $\leftrightarrow$ $[Nb]^3+$ $\leftrightarrow$ $[Nb]^1+$ $\leftrightarrow$ $[Nb]^0$. The average length of the Nb-C1 bond ($d_{Nb-C1}$) in the NbCl$_6$ octahedron is expected to increase along with the valence of Nb. As shown in the TABLE 2, ($d_{Nb-C1}$) shrinks from 2.499 to 2.492 Å and ($d_{Nb2-C1}$) expands from 2.499 to 2.507 Å. This change of the bond lengths is consistent with the charge disproportionation model.

The expansion/shrinking of the cluster bonding length increases/decreases the energy level of the bonding 2$a_1$ orbital (see the schematic view of $2a_1$ molecular orbital of the Nb$_1$ trimer, right side, Figure 7). In the $[Nb]^+$ cluster, the $2a_1$ orbital is occupied by a single $d$ electron. During the oxidation ($[Nb]^3+$ $\rightarrow$ $[Nb]^+$), the $2a_1$ orbital becomes unoccupied, while reduction ($[Nb]^+$ $\rightarrow$ $[Nb]^+$) results in a fully occupied. In the expanded (Nb1)$_3$ trimers and shrunk (Nb2)$_3$ trimers, the energy level of the bonding $2a_1$ decreases and increases, respectively. Therefore, from the point of view of the energy level, the magnetic-nonmagnetic phase transition occurs with the occupation-energy-gain. The energy-dropping $2a_1$ orbital of the Nb1 site becomes fully occupied and the energy-dropping $2a_1$ orbital of the Nb2 site becomes unoccupied (left side, Figure 7). Thus, the observed expansion/shrinking of the cluster bonding strongly demonstrates the charge disproportionation induced by interlayer charge transfer.

Finally, we discuss the origin of the charge disproportionated magnetic-nonmagnetic phase transition. The observed large hysteresis appearing in the cooling and heating processes suggest the strong first-order phase transition, suggesting that the charge disproportionation is not caused by an order-disorder transition of charge or magnetic fluctuation but by the structural phase transition. Thus, it is concluded that the origin of the unconventional phase transition is a lattice instability accompanied by the charge disproportionation, which is also probed by the size effect to suppress the phase transition.

**CONCLUSIONS**
We have succeeded in growing fine single crystals of the cluster magnet Nb$_3$Cl$_8$ by the flux method using the solvent evaporation technique and identified the magnetic-nonmagnetic phase transition at ~100 K. XRD and NMR analyses revealed that the magnetic-nonmagnetic phase transition is driven by a charge disproportionation from layers of paramagnetic [Nb$_3$]$^{8+}$ to alternating layers of nonmagnetic [Nb$_3$]$^{7+}$ and [Nb$_3$]$^{9+}$. Moreover, nanoscale size controlling is found to suppress the magnetic-nonmagnetic phase transition. We believe that the unconventional interlayer charge disproportionation is caused by characteristics of the cluster magnets.

S2
Figure S1: (Color online) Difference of the stacking pattern caused by a stacking shift of the Nb3Cl8 at 300 K (left) and 24 K (right).
2 Microscopic Size Evaluation

Figure S2: SEM photographs of powder sample of Nb$_3$Cl$_8$.

Figure S3: (Color online) Comparison of the effect of crystal size dependence on the 002 peak for single crystal and powder samples of Nb$_3$Cl$_8$. 
Exotic charge disproportionation is found in a cluster compound Nb$_3$Cl$_8$. The charge disproportionation drastically changes the magnetic system from paramagnetic to nonmagnetic. Detailed studies of structure and magnetic properties revealed the origin being the interlayer charge transfer, which results in the unconventional charge arrangement from layers of the paramagnetic [Nb$_3$]$^{8+}$ to alternating layers of nonmagnetic [Nb$_3$]$^{7+}$ and [Nb$_3$]$^{9+}$.
