Type I migration

ABSTRACT

Population synthesis studies into planet formation have suggested that distributions consistent with observations can only be reproduced if the actual Type I migration timescale is at least an order of magnitude longer than that deduced from linear theories. Although past studies considered the effect of the Type I migration of protoplanetary embryos, in most cases they used a conventional formula based on static torques in isothermal disks, and employed a reduction factor to account for uncertainty in the mechanism details. However, in addition to static torques, a migrating planet experiences dynamic torques that are proportional to the migration rate. These dynamic torques can impact on planet migration and predicted planetary populations. In this study, we derived a new torque formula for Type I migration by taking into account dynamic corrections. This formula was used to perform population synthesis simulations with and without the effect of dynamic torques. In many cases, inward migration was slowed significantly by the dynamic effects. For the static torque case, gas giant formation was effectively suppressed by Type I migration; however, when dynamic effects were considered, a substantial fraction of cores survived and grew into gas giants.

1. Introduction

The population of extrasolar planets (Baruteau and Papaloizou, 2013), and perhaps even the solar system (Walsh et al., 2011), provide strong evidence that migration has played a role in shaping planetary systems. Low-mass planets (i.e., those with masses up to that of Neptune) migrate through the excitation of linear density waves in the disk, and through a contribution from the corotation region (i.e., Type I migration). Early analytical work (Tanaka et al., 2002) focused on isothermal disks, in which the temperature was prescribed and fixed. These studies found that migration was always directed inward for reasonable disk parameters, and that migration timescales were much shorter than the disk lifetime; therefore, according to migration theory, all the planets should end up very close to the central star.

While Type I migration has always been linked to linear interactions with the disk, Paardekooper and Papaloizou (2009) showed that corotation torque (or horseshoe drag) in isothermal disks show nonlinear behavior and can be much larger than previous linear estimates, which works against fast inward migration. However, the corotation tends to be prone to saturation and fail to prevent rapid inward migration for most of the cases, since in the absence of a diffusive process, the corotation region is a closed system; therefore, it can only provide a finite amount of angular momentum to a planet.

Several well-established theoretical models of planet formation based on the core accretion scenario adopted a population synthesis approach (e.g., Ida and Lin, 2004, 2008; Mordasini et al., 2009a,b; Ida et al., 2013). Ida and Lin (2004) focused on the influence of Type I migration on planetary formation processes and found that when the effects of Type I migration are taken into account, planetary cores have a tendency to migrate into their host stars before they acquire adequate mass to initiate efficient gas accretion. In order to preserve a sufficient fraction of gas giants around solar-type stars, they introduced a Type I migration reduction factor, where factor magnitudes of smaller than unity work to lengthen the Type I migration timescale relative to those deduced from linear theories. With a range of small factors (~ 0.01), it was possible to produce a planetary $M_p-a$ distribution that was...
qualitatively consistent with observations from a radial velocity survey. While several suppression mechanisms for Type I migration under various circumstances have been suggested (e.g., Paardekooper et al. 2011), the origin of the extremely small reduction factor values remains unknown.

Recently, it was proposed that dynamic corotation torque can also play a role for low-mass planets, especially where static corotation torques saturate. Paardekooper (2014) presented an analysis of the torques on migrating, low-mass planets in locally isothermal disks. They found that planets experience dynamic torques whenever there is a radial gradient in vortensity in addition to static torques, which do not depend on the migration rate. These dynamic torques are proportional to the migration rate and can have either a positive or a negative feedback on migration, depending on whether the planet is migrating with or against the static corotation torque. Moreover, they showed that in disks a few times more massive than the minimum mass solar nebula (MMSN), the effects of dynamic torques are significant to reduce inward migration.

In this study, we deduced a torque formula for Type I migration by taking into account dynamic corrections. Using this formula, we performed population synthesis simulations with and without the dynamic corrections in order to evaluate the migration velocity. Using this formula, we were able to assume a steady state for Eq. 4 to determine \( v_p \), or in other words:

\[
-\nu_p + \frac{2q_d}{\pi qr_d^2 \Omega \Sigma} (\Gamma_{\text{static}} + \Gamma_{\text{dynamic}}) = 0
\]

(5)

2.1. Inviscid case \( \frac{x^2}{r_p^2} \ > 1 \)

We derived \( \nu_p \) by substituting Eqs. 2 and 3 into Eq. 4 as:

\[
\Gamma_{\text{inviscid}} = \frac{1}{1 - (3/2 + p)} mc \Gamma_{\text{static}}
\]

(6)

where, \( mc \) is given by (Pa14 Eq. 20):

\[
m_c = 4q_d x_s / q
\]

(7)

where \( x_s = x_s / r_p \)

2.2. Viscid case \( \frac{x^2}{r_p^2} \ < 1 \)

We derived a quadratic equation of \( \nu_p \) by substituting Eqs. 2 and 3 into Eq. 4 as:

\[
A = \frac{2q_d x^2 r_p}{3q_p} \left( \frac{3}{2} + p \right) = mc \left( \frac{3}{2} + p \right) \frac{\tau_r}{6\tau_p}
\]

(8)

\[
B = -1
\]

(9)

\[
C = \frac{2q_d q}{\pi h^2 r_p \Omega} \gamma_{\text{static}} = \frac{r_p}{\tau_{\text{mig}}} \gamma_{\text{static}}
\]

(10)

where \( h \) is the scale height of the disk, \( \gamma_{\text{static}} = \Gamma_{\text{static}} / \Gamma_0 \) (\( \Gamma_0 = (q/h)^2 \Sigma^2 \Omega^2 \)), and \( \tau_r \) and \( \tau_{\text{mig}} \) are the timescales of diffusion and migration, respectively, as given by (Pa14 Eqs. 10 and 23):

\[
\tau_r = \frac{x^2}{r_p^2}
\]

(11)

\[
\tau_{\text{mig}} = \frac{\pi h^2}{2q_d q \Omega}
\]

(12)

The quadratic formula gives the total torque after dynamic correction:

\[
\Gamma_{\text{viscid}} = \Theta(k) \Gamma_{\text{static}}
\]

(13)

where the function \( \Theta(k) \) is defined by (Pa14 Eq. 30):

\[
\Theta(k) = \frac{1 - \sqrt{1 - 2k}}{k}
\]

(14)

where \( k \) is the coefficients given by (Pa14 Eqs. 31–32):

\[
k = \frac{8}{3\pi} \left( \frac{3}{2} + p \right) \frac{\gamma_{\text{static}} q^2 x^2 r_p \Omega}{h^2 \nu_p} = \left( \frac{3}{2} + p \right) \frac{mc \nu_p \gamma_{\text{static}}}{6\tau_{\text{mig}}}
\]

(15)

The function \( \Theta(k) \) takes a critical value of 2 at \( k = 1/2 \), but for \( k > 1/2 \) it does not take any value, since the inside of the square root of \( \Theta(k) \) becomes negative. This suggests that runaway migration takes place for the case \( k > 1/2 \). Paardekooper (2014) suggested
that the time scale of migration for runaway case would be \( t_{\text{mig}} \), and in such a case, torque for the runaway migration would be:

\[
\Gamma_{\text{rw}} = \frac{q}{4d} \Gamma_0 \tag{17}
\]

The results are consistent with the numerical results of Paardekooper et al. (2011). In their simulation, \( v_p \) rapidly converged to the values obtained here, after a short transient phase (Figs. 7, 8, and 9 in Paardekooper (2014)).

In summary, our new torque formula of Type I migration, taking into account dynamic effects, is given as:

\[
\Gamma_i = \Gamma_{\text{static}} \min \left( \frac{1}{1 - m_c(3/2 + p)} \Theta(k) \right) \tag{18}
\]

\[
= \frac{q}{4d} \Gamma_0 \quad k < 0.5 \tag{19}
\]

Fig. 1 shows the dynamic correction factor at each semimajor axis for embryos with masses of 0.01 \( M_\oplus \), 0.1 \( M_\oplus \), 1.0 \( M_\oplus \), and 10 \( M_\oplus \). The masses of the disks were (a) \( 1/\sqrt{10} \times \text{MMSN} \), (b) \( 1.0 \times \text{MMSN} \), (c) \( \sqrt{10} \times \text{MMSN} \), and (d) \( 10 \times \text{MMSN} \). Except for a close-in small protoplanet, most protoplanets had correction factors of significantly less than 0.1; therefore, Type I migration was generally significantly slowed by dynamic effects.

3. Planet formation and migration model

In our model, we adopted the models of Ida and Lin (2004, 2008) and Ida et al. (2013) for (1) planetesimals’ growth through cohesive collisions, (2) the evolution of planetesimal surface density, (3) embryos’ Type I migration and their stoppage at the disk inner edge (except for a modification of the Type I migration formula to include dynamic correction; see Section 2), and for the gas giants, (4) the onset, rate, and termination (through gap opening and/or global depletion) of efficient gas accretion, and (5) their Type II migration.

3.1. Disk models

We adopted the MMSN model (Hayaschi, 1981) as a fiducial set of initial conditions for planetesimal surface density (\( \Sigma_d \)) and introduced a multiplicative factor (\( f_d \)). For the gas surface density (\( \Sigma_g \)), we adopted the \( r \)-dependence of steady accretion disk with constant viscosity (\( \Sigma_g \propto r^{-1} \)) scaled by that of the MMSN at 10 AU with a scaling factor (\( f_g \)). Following Ida and Lin (2008), we set:

\[
\begin{cases}
\Sigma_d = \Sigma_{d,10} \eta_\text{ice} f_d (r/10 \text{AU})^{-1.5} \\
\Sigma_g = \Sigma_{g,10} f_g (r/10 \text{AU})^{-1.0}
\end{cases} \tag{20}
\]

where normalization factors \( \Sigma_{d,10} = 0.32 \text{ g/cm}^2 \) and \( \Sigma_{g,10} = 75 \text{ g/cm}^2 \), and the step function was \( \eta_\text{ice} = 1 \) inside the ice line at \( a_{\text{ice}} \) and 4.2 for \( r > a_{\text{ice}} \).

Neglecting the detailed energy balance in the disk (Chiang and Goldreich, 1997), we adopted the equilibrium temperature distribution of optically thin disks given by Hayaschi (1981), such that:

\[
T = 280 \left( \frac{r}{1 \text{AU}} \right)^{-1/2} \left( \frac{L_*}{L_\odot} \right)^{1/4} \text{K} \tag{21}
\]

Figure 1. Dynamic correction factor at each semimajor axis for 0.01 \( M_\oplus \), 0.1 \( M_\oplus \), 1.0 \( M_\oplus \), and 10 \( M_\oplus \) from top to bottom in each panel. The mass of the disks are (a) \( 1/\sqrt{10} \times \text{MMSN} \), (b) \( 1.0 \times \text{MMSN} \), (c) \( \sqrt{10} \times \text{MMSN} \), and (d) \( 10 \times \text{MMSN} \).
where \( L_\odot \) and \( L_\odot \) are stellar and solar luminosity. We set the ice line to be that determined by an equilibrium temperature in optically thin disk regions:

\[
a_{\text{ice}} = 2.7 \left( \frac{L_\star}{L_\odot} \right)^{1/2} \text{AU} \quad (22)
\]

Owing to viscous diffusion and photoevaporation, \( f_g \) decreases with time. For simplicity, we adopted:

\[
f_g = f_{g,0} \exp \left( -\frac{t}{\tau_{\text{dep}}} \right) \quad (23)
\]

where \( f_{g,0} \) is the initial value of \( f_g \) and \( \tau_{\text{dep}} \) is the gas depletion timescale.

3.2. From oligarchic growth to isolation

On the basis of the oligarchic growth model (Kokubo and Ida, 1998, 2002), the growth rate of embryos/cores at any location, \( a \), and time \( t \), in the presence of disk gas, was described by:

\[
dM_c \frac{dt}{c_{\text{acc}}} = \frac{M_c}{\tau_{\text{c,acc}}} \quad (24)
\]

where

\[
\tau_{\text{c,acc}} = 3.5 \times 10^5 \eta_{\text{ice}} f_d f_g^{-2/3} \left( \frac{a}{1 \text{AU}} \right)^{5/2} \left( \frac{M_*}{M_\odot} \right)^{1/3} \left( \frac{M_c}{M_\odot} \right)^{-1/6} \text{yr} \quad (25)
\]

where \( M_* \) is the mass of the embryo/core. Furthermore, we set the mass of typical field planetesimals to be \( m = 10^{20} \text{g} \).

We computed the evolution of \( \Sigma_g \) distribution due to accretion by all emerging embryos in a self-consistent manner. The growth and migration of many planets were integrated simultaneously with the evolution of the \( \Sigma_g \)-distribution.

During the early phase of evolution, embryos are embedded in their natal disks. Despite their mutual gravitational perturbation, embryos preserve their circular orbits owing to gravitational drag from disk gas (Ward, 1993) and dynamic friction from residual planetesimals (Stewart and Ida, 2000). After the disk gas is severely depleted, the efficiency of the eccentricity damping mechanism is reduced, and the embryos’ eccentricity grow until they cross each other’s orbits (i.e., giant impact). However, in this study, growth via the giant impact process was not considered. Moreover, we also ignored dynamic interaction between planets, with the growth of individual planets integrated independently.

3.3. Type I migration

Type I migration of an embryo is caused by the sum of tidal torque from disk regions that are both interior and exterior to the embryos. The rate and direction of embryos’ migration are determined by the differential Lindblad and corotation torques. While a conventional formula of Type I migration, which assumes locally isothermal disks (Tanaka et al., 2002), shows that the migration is always inward, recent developments have shown Type I migration of isolated embryos in non-isothermal disks; therefore, the magnitude and sign of tidal torque can be changed. Ida and Lin (2008) used the conventional formula of Type I migration in isothermal disks derived by Tanaka et al. (2002) with a scaling factor \( C_1 \) of:

\[
dr \frac{dt}{dt} = C_1 \times 1.08 (p + 0.80q - 2.52) \frac{M_p}{M_*} \frac{\Sigma_g r^2}{M_\odot} \left( \frac{r}{r_K} \right)^2 r \Omega_K \quad (26)
\]

where \( p = d \log \Sigma_g / d \log r, q = d \log \Sigma_g / d \log r \), \( c_s \) is the sound speed, and \( r_K \) is the Keplerian angular velocity. The expression of Tanaka et al. (2002) corresponds to \( C_1 = 1 \), and for slower migration, \( C_1 < 1 \). While we derived a new torque formula for Type I migration that included dynamic corrections (see Section 2), for comparison we also used the conventional formula with the scaling factor \( C_1 = 1.0 \).

We assumed that Type I migration ceases inside the inner boundary of the disk, because at this point \( f_g \) is locally zero. For computational convenience, we set the disk inner boundary to be the edge of the magnetospheric cavity at 0.04 AU.

3.4. Formation of gas giant planets

Models for the formation of gas giant planets were the same as those used in Ida et al. (2013). Embryos were surrounded by gaseous envelopes when their surface escape velocities became larger than the sound speed of the surrounding disk gas. When their mass grew (through planetesimal bombardment) above a critical mass:

\[
M_{\text{c,hydro}} = 10 \left( \frac{M_c}{10^{-6} M_\odot \text{yr}^{-1}} \right) ^{0.25} \quad (27)
\]

both the radiative and convective transport of heat became sufficiently efficient to allow their envelope to contract dynamically (Ikoma et al., 2000).

In the above equation, we neglected the dependence on opacity in the envelope (Hori and Ikoma, 2010). In regions where cores have already acquired isolation mass, their planetesimal-accretion rate \( (\dot{M}_c) \) would be much diminished (Ikoma et al., 2000) and \( M_{\text{c,hydro}} \) would be comparable to an Earth-mass, \( M_\oplus \). However, gas accretion also releases energy and its rate is still regulated by the efficiency of radiative transfer in the envelope, such that:

\[
dM_p \frac{dt}{\tau_{\text{KH}}} = \frac{M_p}{\tau_{\text{KH}}} \quad (28)
\]

where \( M_p \) is the planet mass including gas envelope. According to Ida and Lin (2008), we approximated the Kelvin-Helmholtz contraction timescale, \( \tau_{\text{KH}} \), of the envelope using:

\[
\tau_{\text{KH}} = 10^9 \left( \frac{M_p}{M_\odot} \right)^{-3} \quad (29)
\]

Eq. 28 shows that \( dM_p / dt \) rapidly increases as \( M_p \) grows; however, this is limited by the global gas accretion rate throughout the disk and by the process of gap formation near the protoplanets’ orbits. The disk accretion rate can be expressed as:

\[
M_{\text{disk}} \approx 3 \times 10^{-9} f_g \left( \frac{\alpha}{10^{-3}} \right) M_\odot \text{yr}^{-1} \quad (30)
\]

where \( \alpha \) is a parameter of a power law for turbulent viscosity (Shakura and Sunyaev, 1972). During the advanced stage of disk evolution, we assumed that both \( M_{\text{disk}} \) and \( \Sigma_g \) evolved in proportion to \( \exp(-t/\tau_{\text{dep}}) \). The rate of accretion onto the cores cannot exceed \( M_{\text{disk}} \).

A gap, or at least a partial gap, is formed when a planet’s tidal torque exceeds the disk’s intrinsic viscous stress (Lin and Papaloizou, 1985). This viscous condition for gap formation is satisfied for planets with:
where $C_2$ is an efficiency factor associated with the degree of asymmetry in the torques between the inner and outer disk regions. If the inner disk is severely depleted, $C_2 = 1$. We treated the factor $C_2$ as a model parameter, and we set $C_2 = 0.1$.

4. Population synthesis of planetary systems

Using our new torque formula for Type I migration, we modeled the formation of planetary systems using Monte Carlo simulations. The predicted mass and period distributions were compared with those from a conventional Type I migration model.

4.1. Numerical settings

We first generated a set of 1000 disks with various values of $f_{g,0}$ (the initial value of $f_g$) and $t_{\text{dep}}$. We adopted a range of disk model parameters that represented the observed distribution of disk properties and assigned them to each model with an appropriate statistical weight. For the gaseous component, we assumed that $f_{g,0}$ had a lognormal distribution centered on $f_{g,0} = 1$ with a dispersion of 1 and an upper cutoff at $f_{g,0} = 30$, independent of the stellar metallicity. For heavy elements, we choose $f_{g,0} = 10^{-3} \text{Fe}/\text{H}_{\odot}$, where $\text{Fe}/\text{H}_{\odot}$ is the metallicity of the disk. We assumed that these disks had the same metallicities as their host stars. We also assumed that $t_{\text{dep}}$ had log-uniform distributions in the range $10^6$–$10^7$ yr.

For each disk, 15 values of $a$ for the protoplanetary seeds were selected from a long-uniform distribution in the range 0.05–30 AU, assuming that the mean orbital separation between planets was 0.2 on a logarithmic scale. Constant spacing in the logarithm corresponded to the spacings between the cores, which were proportional to $a$. This represented the simplest choice and a natural outcome of dynamic isolation at the end of oligarchic growth.

In all simulations, the values $a = 10^{-3}$ and $M_{\ast} = 1M_{\odot}$ were assumed. Since ongoing radial velocity surveys are focused on relatively metal-rich stars, we presented our results with [Fe/H] = 0.1.

We artificially terminated Type I and Type II migration near the disk inner edge at 0.04 AU. We did not specify a survival criterion for the close-in planets because we lacked adequate knowledge about planets’ migration and their interaction with host stars near the inner edge of their nascent disks. Hence, we recorded all of the planets that migrated to the vicinity of their host stars. In reality, a large fraction of the giant planets that have migrated to small disk radii were either consumed (Sandquist et al., 1998) or tidally disrupted (Trilling et al., 1998) by their host stars. Cores that migrate to the inner edge of the disk may also coagulated and form super-Earths (Ogihara and Ida, 2009); however, this was not considered in our simulations.

4.2. Simulated individual systems

We compared the time evolution of planetary masses and semimajor axes for the new torque formula model (Figs. 2a and 3a) and the conventional torque formula model with $C_1 = 1.0$ (Figs. 2b and 3b). We choose a disk a few times more massive ($f_{g,0} = 6.0$ and 8.0) than the minimum solar nebula, and with $t_{\text{dep}} = 3 \times 10^9$ yr. The results showed that inward migration of planet embryos was slowed significantly by dynamic effects. When dynamic effects were considered, some cores survived and grew into gas giants; however, when considering only static torque, all cores migrated to the vicinity of their central star before growing enough to accrete the nebula gas.
\[ GI = G_{\text{static}} = \min \left( \frac{1}{1 - m_c(3/2 + p)} \Theta(k) \right) \]  

(38)

with the mass of each planet embryo. The correction factors remained small (\(<0.1\)) throughout the simulation; therefore, the dynamic correction of Type I migration effectively prevented embryos from migrating to the central star.

### 4.3. Distributions of mass and semimajor axes

We compared the predicted \( M_p - a \) distributions using the new torque formula (Fig. 5a) and the conventional formula with \( C_1 = 1.0 \) at \( t = 2 \times 10^7 \) yr. In order to directly compare the theoretical predictions with the observed data, we plotted values of \( M_p \) that were 1.27 times the values of \( M_p \sin i \), as determined from radial velocity measurements (Fig. 5c). This correction factor corresponded to mean values of \( 1/(\sin i) = 4/\pi \) for a sample of planetary systems with randomly oriented orbital planets. To compare the theoretical results with \( M^* = 1M_\odot \), we plotted only the data of planets around stars with \( M^* = 0.8 - 1.2M_\odot \) that have been observed by radial velocity surveys.\(^1\)

For the conventional models, the formation probability of gas giants dramatically changed with \( C_1 \) (Ida and Lin, 2008). Within the limits of Type I migration with an efficiency comparable to that deduced from the traditional linear torque analysis (i.e., with \( C_1 = 1 \); Fig. 5b), all cores were cleared prior to gas depletion, such that gas giant formation was effectively suppressed. However, when considering the dynamic effects, a substantial fraction of the cores survived and grew into large gas giants (Fig. 5a). We carry out a Kolmogorov-Smirnov (K-S) test for statistical similarity between the predicted \( M_p - a \) distributions and the observed data for the

\(^1\) See http://exoplanet.eu/.
The determined value of parameter domain of 0.1 AU < a < 5 AU and $M_p > 100 M_\oplus$. While the conventional model produces no giant planets (Fig. 5b), the predicted $M_p - a$ distribution using the new torque formula (Fig. 5a) is statistically similar to the observed data (Fig. 5c) within a significance level of $p$-value > 0.05 for both the semimajor axis and mass cumulative distribution functions.

Without considering the dynamic correction for Type I migration, when a planet’s mass exceeded that of Earth, the corotation torque became smaller owing to saturation. At this point, static torque affected the planet more efficiently so that its inward migration was rapid. However, when the dynamic correction was included, the migration timescale was short, and the saturation of the corotation torque was less effective. Under these conditions, inward migration slowed, which allowed for the formation of gas giants before migration to the central star.

In summary, population synthesis simulations using our new torque formula with dynamic correction (Fig. 5a) can explain the gas giants (>100$M_\oplus$) observed in exoplanetary systems (Fig. 5c). In contrast, simulations using a conventional formula ($C_1 = 1.0$; Fig. 5b) cannot explain the observed data. These results show that planet populations consistent with observations can be reproduced naturally (i.e., without considering the reduction factor) if we take into account dynamic corrections for Type I migration torque.

5. Conclusions

We derived a new torque formula for Type I migration by taking into account dynamic corrections. Using this formula, we performed population synthesis simulations with and without the effects of dynamic torques. In most cases, inward migration was significantly slowed by the dynamic effects. Considering just static torques, gas giant formation was effectively suppressed by Type I migration of cores; however, when dynamic effects were considered, a substantial fraction of cores survived and grew into gas giants.

Appendix. Static Torque formula

Static torque (Pa11 and CN14) is given by

$$\Gamma_{\text{static}} = \Gamma_{\text{LR}} + \left[ \Gamma_{\text{VHS}} f(p_x) G(p_x) + \Gamma_{\text{EHS}} f(p_x) F(p_x) \right] \times \sqrt{G(p_x) G(p_x)} + \Gamma_{\text{LVCT}} (1 - K(p_x))$$

$$+ \Gamma_{\text{LECT}} \left( (1 - K(p_x)) \left( 1 - K(p_x) \right) \right) F_0 f_i \left( A_5 \right) \left( A_1 \right)$$

(1)

where $\Gamma_{\text{LR}}$, $\Gamma_{\text{VHS}}$, $\Gamma_{\text{EHS}}$, $\Gamma_{\text{LVCT}}$, and $\Gamma_{\text{LECT}}$ are the Lindblad torque, vortensity and entropy related horseshoe drag torques, and linear vortensity and entropy related corotation torques, respectively, as given by Eqs. 3–7 in Paardekooper et al. (2011):

$$\Gamma_{\text{LR}} = (-2.5 - 1.7\beta + 0.1\alpha) G_0 / \gamma_{\text{eff}}$$

(2)

$$\Gamma_{\text{VHS}} = [1.1(3/2 - \alpha)] G_0 / \gamma_{\text{eff}}$$

(3)

$$\Gamma_{\text{EHS}} = 7.9 \left( \xi / \gamma_{\text{eff}} \right) G_0 / \gamma_{\text{eff}}$$

(4)

$$\Gamma_{\text{LVCT}} = [0.7(3/2 - \alpha)] G_0 / \gamma_{\text{eff}}$$

(5)

$$\Gamma_{\text{LECT}} = \left( (2.2 - 1.4 / \gamma_{\text{eff}}) \right) G_0 / \gamma_{\text{eff}}$$

(6)

where $\alpha = d \ln \Sigma / d \ln r$, $\beta = d \ln T_{\text{inl}} / d \ln r$, and $\xi = \beta - (\gamma_{\text{eff}} - 1) \alpha$.

Here, $G_0 = (q/\hbar)^2 \Sigma r^4 \Omega^2$.

The functions $f(p_x), G(p_x), F(p_x), K(p_x)$ and $K(p_x)$ are related to the ratio between the viscous/thermal diffusion time scale and horseshoe libration/horseshoe U-turn time scales, given by Eqs. 21, 23 and 30 in Paardekooper et al. (2011):
\[ F(p) = \frac{1}{1 + (p/1.3)^2} \]  
\[ G(p) = \frac{16}{25} \left( \frac{45\pi}{8} \right)^{3/4} p^{3/8} p < \sqrt{\frac{8}{45\pi}} \]  
\[ 1 - \frac{9}{25} \left( \frac{8}{45\pi} \right)^{3/4} p^{3/8} p > \sqrt{\frac{8}{45\pi}} \]  
\[ K(p) = \frac{16}{25} \left( \frac{45\pi}{28} \right)^{3/4} p^{3/8} p < \sqrt{\frac{8}{45\pi}} \]  
\[ 1 - \frac{9}{25} \left( \frac{28}{45\pi} \right)^{3/4} p^{3/8} p > \sqrt{\frac{8}{45\pi}} \]  
\[ P = \frac{2}{3} \sqrt{\frac{2\pi Q}{r^3}} \]  
\[ P = \sqrt{\frac{2\pi Q}{r^3}} \]  
\[ x = C \sqrt{\frac{q}{h}} \]  
\[ C = \frac{1.1}{\gamma_{\text{eff}}} \left( \frac{0.4}{b/h} \right)^{-1/4} \]  
\[ \chi = \frac{4\gamma(\gamma-1)}{3D^2 \rho H^2 \Omega} \]  
\[ \gamma_{\text{eff}} = \frac{2Q\gamma}{\gamma Q + \frac{1}{2} \sqrt{2\gamma Q^2 + 1} - 16Q^2(\gamma - 1) + 2\gamma Q^2 - 2} \]  
\[ Q = \frac{2\chi}{3\rho H^2 \Omega} \]  
\[ F_e = \exp \left( -\frac{e}{e_t} \right) \]  
\[ F_i = 1 - \tanh(i/h) \]  
\[ F_L = \left[ P_e \times \frac{P_e}{P_i} \right] \left( 0.07 \frac{i}{h} + 0.085 \left( \frac{i}{h} \right)^4 - 0.08 \left( \frac{e}{h} \right) \left( \frac{i}{h} \right)^2 \right] \]  
where \( P_i \) is defined as \( P_i = \frac{1 + (e/\tan(i/h))^2}{1 - (e/\tan(i/h))^4} \).
