Three-way catalyst, Rh catalyst, Operando, XAS, XANES, EXAFS

ABSTRACT: The dynamic behavior of Rh species in 1 wt% Rh/Al₂O₃ catalyst during the three-way catalytic reaction was examined using a micro gas chromatograph, a NO_x meter, a quadrupole mass spectrometer, and time-resolved quick X-ray absorption spectroscopy (XAS) measurements at a public beamline for XAS, BL01B1 at SPring-8, *operando*. The combined data suggest different surface rearrangement behavior, random reduction processes, and autocatalytic oxidation processes of Rh species when the gas is switched from a reductive to an oxidative atmosphere and vice versa. This study demonstrates an implementation of a powerful *operando* XAS system for heterogeneous catalytic reactions and its importance for understanding the dynamic behavior of active metal species of catalysts.

1. INTRODUCTION

Platinum group metal (PGM) elements such as Rh, Pd, and Pt are frequently used as essential components of three-way catalysts (TWCs) for purification of harmful gases such as nitrogen oxides (NO_x), carbon monoxide (CO), and hydrocarbons (HCs) in automobile exhaust gas. The total demand for Rh, Pd, and Pt for TWCs in 2012 was about 80%, 70%, and 40% of available materials, respectively.¹ On the other hand, the number of automobiles worldwide reached 1.2 billion by the end of 2014, as reported by the Japan Automobile Manu-

facturers Association, Inc.,² and has been increasing every year. Further, regulations on exhaust gas emissions have become more restrictive with time. Therefore, the reduction of PGM element use for TWCs has been among the urgent global issues to arise in response to the trend of increasing demand for automobiles worldwide and the need to protect the global environment.

The high demand for Rh for TWCs stems from its outstanding catalytic activity in the reduction of toxic NO_x to nontoxic nitrogen (N₂). To reduce Rh usage for economic and environ-

mental reasons, it is very important to understand the fundamental behavior of Rh species (i.e., oxidation, reduction, aggregation, etc.) under working conditions, or *operando*. Although an enormous number of studies have already been performed on the mechanism of catalysis, degradation, and regeneration of Rh-based TWCs for several decades,³ further research is still needed.

The term *operando*, or especially *operando* spectroscopy, is a generic concept describing application of spectroscopic techniques to materials in their working state (e.g., a catalyst at work) to elucidate the relationships among function, structure, and/or the electronic states. Researchers generally study the relationships between the catalytic performance and dynamic behavior of TWCs using various gas molecules. For this purpose, IR spectroscopy has been one of the most widely used techniques to clarify the catalysis mechanism by identifying the intermediate adsorbed species on catalysts.⁴ However, IR spectroscopy can observe only gaseous or adsorbed molecules. The dynamic behavior of catalytically active metal species at very high temperature and under both oxidative and reductive atmospheres are of interest to understand the true active sites for catalysis such as three-way catalysis.

For example, so-called *in situ* or environmental transmission electron microscopy (TEM) is an emerging technique to directly observe small targets such as PGM nanoparticles on supports under a very low-pressure environment.⁵ However, the applicable pressure is usually much lower than atmospheric pressure, which is far from the realistic conditions for TWCs. Among various analytical techniques, X-ray spectroscopy has been most successfully applied for *in situ* studies, especially for reactions under harsh conditions such as three-way catalysis. The most common analytical technique that utilizes X-rays as a probe is X-ray diffraction (XRD). XRD is a powerful technique for reaction monitoring under both common, *ex situ* conditions and *in situ* conditions because of its penetrating power. For example, Jozwiak et al. studied the reduction behavior of iron oxides with hydrogen or carbon monoxide by an *in situ* XRD technique in combination with conventional temperature-programmed reduction and thermogravimetry-differential thermal analysis techniques, and clarified the temporal variation of the composition of iron oxide species.⁶ Bao et al. used *in situ* XRD⁷⁻⁸ to elucidate the effect of confinement of iron oxides in carbon nanotubes on their activity in Fischer–Tropsch synthesis.⁹ However, the particle sizes of the metal species in these cases are typically around or no less than 10 nm. The XRD technique is inherently unsuitable for sensitive analysis of very small particles (sizes less than a few nanometers). Thus, monitoring Rh species that exist in 1 wt% Rh/Al₂O₃ is usually outside the scope of the XRD technique.

On the other hand, X-ray absorption spectroscopy (XAS) can be utilized to study the redox behavior and structural changes of such very small species. In principle, XAS also has a high penetrating power and element specificity. A high degree of freedom for the sample environment enables the combination of XAS with other spectroscopic techniques such as IR spectroscopy. For example, Newton et al. at the European Synchrotron Radiation Facility, Grenoble, France, in association with various research groups, extensively applied *operando* spectroscopy in combination with XAS and other techniques [e.g., diffuse reflectance infrared spectroscopy (DRIFT)] to various heterogeneous catalysts, especially TWCs

and related materials,¹⁰⁻¹⁷ to study alcohol oxidation for more than a decade. Grunwaldt and Baiker and their colleagues have reported *operando* XAS studies of Rh and Rh-based catalysts under the methane oxidation reaction even with flow direction or two-dimensional resolution and observed the detailed spatial distribution of the Rh state at approximately the ignition temperature.¹⁸⁻²⁴ These excellent studies focused on the bulk states of PGM species and adsorbed small molecules to understand the elementary reactions and specific dynamic behavior of the catalysts, and have yielded deep insights into the reaction mechanism under well-controlled model conditions.

In this work, the dynamic behavior of Rh species in a model Rh-based catalyst, 1 wt% Rh/Al₂O₃, under relatively idealized conditions has been extensively studied for the first time by simultaneous quantitative observation of the eluent gas and use of a quick XAS measurement system at a public beamline, BL01B1, at SPring-8.²⁵ The different gases were quantified using a micro gas chromatograph (GC), a NO_x meter, and a quadrupole mass (Q-Mass) spectrometer. We focused on the relationship between the catalytic activity in the reduction of NO_x species and the surface and bulk dynamics of Rh species to obtain insight into the fundamental attributes of a Rh-based TWC. We found that the reaction steps of oxidation and reduction of surface Rh species involve two-step autocatalytic oxidation by a Finke–Watzky-type nanoparticle formation mechanism and simple one-step pseudo-first-order kinetics.

2. EXPERIMENTAL DETAILS

2.1. Preparation of 1 wt% Rh/Al₂O₃. Rh/Al₂O₃ (1 wt%) was prepared by a commonly used impregnation method. A portion of Rh acetylacetonate (0.08 g, 0.02 g on Rh metal basis) was dissolved in ethyl acetate (18 mL) in an evaporating dish, and γ -Al₂O₃ (JRC-ALO-7, 1.98 g) was added to the Rh solution. The mixture was heated in a water bath to 80 °C and continuously stirred with a glass rod to dryness. Subsequently, the dried sample was calcined at 500 °C for 3 h. All materials except for γ -Al₂O₃ were purchased from Wako Pure Chemical Industries, Ltd. and used as received. γ -Al₂O₃ was kindly provided by the Catalysis Society of Japan. Temperature programmed reaction of the three-way catalytic reaction (TWCR) over this catalyst was performed at our laboratory (Figures S1 and S2). We cannot find any evident Rh particles in the as-prepared and spent catalysts by TEM measurements (Figure S3).

2.2. XAS measurement. Rh *K*-edge XAS measurements were conducted at a public beamline, BL01B1,²⁵ SPring-8 (Japan Synchrotron Radiation Research Institute, Hyogo, Japan). The incident X-rays were monochromatized with a Si(311) double crystal monochromator. Higher harmonic X-rays were removed by setting the glancing angle of the Rh-coated X-ray mirrors to 1.5 mrad. The incident (*I*₀) and transmitted (*I*₁) X-ray fluxes were measured using ion chambers filled with Ar (100%) and Ar (50%)/Kr (50%), respectively. Conventional Rh *K*-edge XAS spectra of a Rh metal foil and Rh₂O₃ were collected as reference data. Rh₂O₃ was mixed with an appropriate amount of boron nitride, pressed into a pellet, and used for XAS measurement. The photon energy was calibrated at the inflection point of the Pd *K*-edge X-ray absorption near-edge structure (XANES) spectrum of Pd metal foil to 24,350 eV. Data were reduced using the Athena and Artemis software ver. 0.9.25 included in the Demeter package.²⁶

Operando XAS measurements were performed at the same beamline, BL01B1, using a high sampling rate thermal con-

ductivity detector GC (490 Micro GC, Agilent Technologies Inc.) for quantification of CO, C₃H₆, N₂, CO₂, O₂, and N₂O; a NO_x meter (ECL-88AO Lite, Anatec Yanaco Inc.) for quantification of NO_x species; and a Q-Mass spectrometer (BEL-Mass, MicrotracBEL Corp.) for semi-quantitative analysis of the eluent gas. The acquisition time for one XAS spectrum was approximately 3 min. A schematic view of the *operando* XAS setup is shown in Scheme 1.

Scheme 1. Simplified view of *operando* XAS setup.

To secure the gas flow path, 200 mg of 1 wt% Rh/Al₂O₃ (25/50 mesh) was directly pelletized (φ10 mm, thickness ca. 3 mm) inside a modified heating XAS cell (ASPF-20-03, Kyowa Vacuum, Figure S4). The incident X-rays penetrated the center of the sample with a beam size of approximately 4 mm (horizontal) × 1 mm (vertical). Thus, the observed Rh state was averaged in the gas flow and X-ray directions. The catalyst was pretreated under He flow at 400 °C for 30 min. Immediately after pretreatment, the TWCR was tested. The reaction model gas (100 mL min⁻¹) contained NO (1000 ppm), CO (1000 ppm), C₃H₆ (250 ppm), O₂ (912.5–1337.5 ppm), and He balance. The concentration of O₂ was varied between 912.5 and 1337.5 ppm during the reaction. The stoichiometric condition was achieved when the concentration of O₂ was set to 1125 ppm, on the basis of the chemical equation shown below.

For clarity, the lambda parameter is introduced as an indicator of the oxygen concentration or stoichiometric balance:

$$\lambda = \frac{[\text{NO}]_a + [\text{CO}]_a + [\text{O}_2]_a \times 2}{[\text{NO}]_s + [\text{CO}]_s + [\text{O}_2]_s \times 2}$$

where [X]_y is the concentration of X in the actual (y = a) or stoichiometric condition (y = s).

The reaction was performed following the oxygen profile illustrated in Figure 1 shown below. First, the leanest gas (λ = 1.1) was introduced into the XAS cell, and the λ value of the inlet gas was decreased by 0.05 every 20 min for 1 h 40 min to the richest gas among all the conditions (λ = 0.9). Subsequently, the λ value of the inlet gas was increased in the same manner to 1.1 in another 1 h 20 min. After the first lean-rich-lean cycle, the λ value was decreased abruptly to 1.0 and 0.9 successively and increased again to 1.0 and then to 1.1. The reaction time was 4 h 20 min. For clarity, we use a 24 h clock notation as if the reaction started at 0:00, unless otherwise stated.

3. RESULTS

In this section, the catalytic activity of 1 wt% Rh/Al₂O₃ is discussed on the basis of the GC and NO_x profiles. Subsequently, the dynamic behavior of Rh species is estimated from the temporal variation of a series of XANES spectra, and several selected Fourier transforms of extended X-ray absorption fine structure (EXAFS) spectra with characteristic changes are also discussed. A comprehensive interpretation is given in chronological order in the Discussion section.

3.1. Catalytic activity. Figure 1 shows the eluent gas concentration as quantified by the micro GC at approximately 3 min intervals, the NO_x meter, and the corresponding profile of λ (O₂ concentration indicator). This overall profile at the XAS beamline, BL01B1, SPring-8, was essentially identical to that recorded at our laboratory (not shown), which ensured that the experiment was indeed performed *in operando*, at least from the viewpoint of catalytic activity assessment. The sum of the NO_x species and reduced N₂ gas was close to 1000 ppm as the NO basis throughout the reaction. This means that negligible amounts of other nitrogen-related species such as N₂O or NO₂ were generated, at least under the present high-temperature conditions, which is consistent with the Q-Mass profile (Figure S5). It is evident that the production rate of N₂ over 1 wt% Rh/Al₂O₃ at 400 °C under lean conditions was less than 100%, at approximately 70%–80% (0:00–0:40). Note, however, that the first GC analysis result showed that the N₂ concentration just after the gas was introduced (0:03) was slightly higher than that before the first gas switch (0:20). A gradual change in the amount of NO_x was also observed initially. In addition, a small amount of O₂ was observed in the later stages of the first period (0:10–0:20). These results indicate that the Rh surface was oxidized in the first 10 min and lost its catalytic activity upon reduction of NO. When the feed gas composition became stoichiometric (λ = 1.0), or under the rich condition, the NO gas was quantitatively decomposed into N₂ (0:40–2:20). On the other hand, the appearance of CO and a small decrease in the amount of CO₂ in the eluent gas were observed under the rich condition (1:20–2:00). We believe that this phenomenon may be attributed to the water-gas shift reaction (WGS) after the TWCR was complete, as discussed in the Supporting Information.

After the feed gas composition returned to the lean condition, the production rate of N₂ decreased to either 80% or 60% (2:20–3:00). In addition, a small amount of O₂ gradually appeared (2:40–3:00) under the leanest condition. Gradual changes in the amount of NO_x were also observed at the points where the feed gas composition was switched from a stoichiometric to a lean condition at around 2:20 or 4:00, and from a lean to a stoichiometric condition at around 3:00 or 4:20. Note that the increase in the amount of NO_x during the change from stoichiometric to lean conditions exhibited sigmoidal curves and was slower than that during the change from lean to stoichiometric conditions, which may be regarded as an exponential curve. We believe that these phenomena reflect the surface redox behavior of Rh species.

A detailed kinetic analysis is given in the Discussion section. During the second lean-rich-lean cycle (2:40–4:20), the NO reduction rate increased to approximately 90% (3:00) and was kept near 100% before the last lean condition (4:00–4:20), which showed only 60% conversion from NO to N₂.

In brief, the GC profile for the TWCR over 1 wt% Rh/Al₂O₃ was identical to that obtained in the laboratory experiment. Furthermore, interesting behavior was observed at each gas

switching point and under rich conditions. The different profiles of the NO reduction rate at the gas composition switching

Figure 1. GC and NO_x profiles of the eluent gases and time course of the metallic or oxidized Rh species ratio estimated by linear combination fitting analysis of the Rh *K*-edge XANES spectra during the TWCR over 1 wt% Rh/Al₂O₃ at 400 °C during *operando* XAS measurement, with λ (O₂ concentration) profile. (Note: N₂O was not observed throughout the reaction.)

points implied dynamic redox behavior of the Rh species.

3.2. Dynamic redox behavior of Rh species. The temporal variation of metallic or oxidized Rh species, as estimated by linear combination fitting (LCF) analysis using a series of Rh *K*-edge XANES spectra of 1 wt% Rh/Al₂O₃, is also shown in Figure 1. Note that Figure 1 shows the *trend* of the redox behavior of the total Rh species, but not the actual redox degree of the Rh species (i.e., Rh⁰ or Rh³⁺). Linear combination fitting analysis was performed using the initial XANES spectrum before He pretreatment, which represents an oxide-like Rh species of the calcined Rh/Al₂O₃, and the XANES spectrum of the most reduced state after the second rich condition at around 3:45. We did not use the XANES spectra of Rh foil and bulk Rh₂O₃ for the LCF analysis because the XANES spectrum of Rh foil usually does not represent that of the small Rh nanoparticles discussed here. The complete profile of the Rh *K*-edge XANES spectra and the time course of the metal-like or oxide-like Rh species ratio including the pretreatment step are provided in the Supporting Information (Figures S6 and S7). During pretreatment, the amount of oxide-like Rh species was reduced by 60%. After the lean feed gas was initially introduced, the oxidized Rh species increased rapidly in approximately 10 min, and 90% of the Rh species were oxidized. After the oxidation process, the electronic state of the average Rh species remained unchanged before the rich condi-

tion (0:10–1:00) and even under the stoichiometric condition. However, the introduction of rich feed gas initiated an initially rapid and then slow reduction of the Rh species (1:00–2:00). This behavior can be interpreted as the occurrence of a gradual reduction process from the surface to the core of the Rh species. When the feed gas composition was changed to the stoichiometric and lean conditions again, 80% of the Rh species were gradually oxidized (2:00–3:00). The difference in the oxidation ratio between the first and second lean conditions (90% and 80%, respectively) can be explained by agglomeration of Rh species, which leads to a decrease in the specific surface area under a reductive atmosphere.

In addition, the R factors obtained by LCF analysis from 2:20 to 3:20 were significantly larger than those in the other periods (Figure S8). This fact implies that the spectral standards used in the LCF analysis may be insufficient; in other words, there may be a third Rh component. Taking into account the aggregation process of Rh species, we can assume the three Rh components to be metal-like Rh, oxide-like Rh on the surface of Rh particles (surface Rh oxide), and oxide-like Rh in Rh particles (bulk Rh oxide) in comparison of the standard spectra for LCF with those of Rh metal and Rh₂O₃ (Figure S5). However, it is very difficult to distinguish the surface Rh oxide from the bulk Rh oxide using the XANES spectra, thus ignored at the present study.

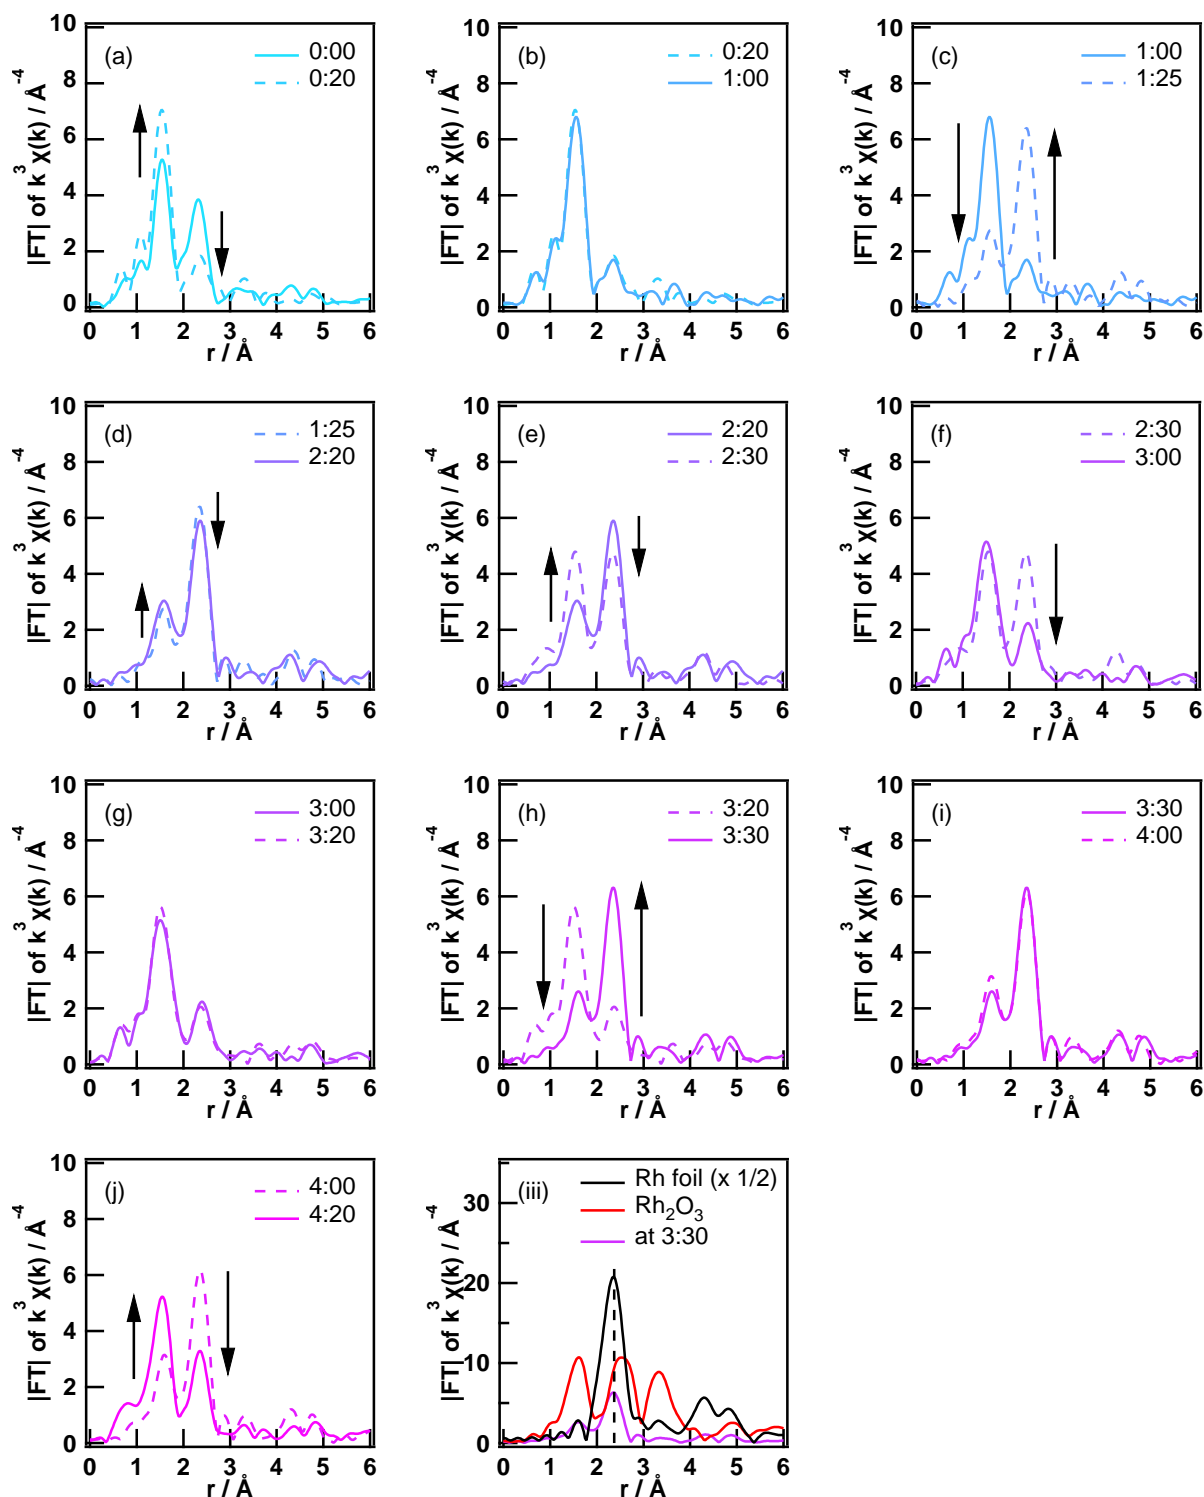

Figure 2. Fourier transform of Rh *K*-edge EXAFS spectra (phase-uncorrected, k -range: $3\text{--}13\text{ \AA}^{-1}$) of 1 wt% Rh/Al₂O₃ during *operando* XAS measurement. (a) 0:00–0:20, (b) 0:20–1:00, (c) 1:00–1:25, (d) 1:25–2:20, (e) 2:20–2:30, (f) 2:30–3:00, (g) 3:00–3:20, (h) 3:20–3:30, (i) 3:30–4:00, (j) 4:00–4:20, and (k) Rh metal foil, Rh₂O₃, and the sample spectrum at 3:30.

During the second lean-rich-lean cycle (2:40–4:20), the redox behavior of the Rh species was essentially identical to that observed during the first lean-rich-lean cycle. In addition, the redox behavior of the Rh species under the stoichiometric condition apparently depends on whether the previous condition was lean or rich.

The oxidation state of the Rh species under the stoichiometric condition after the lean condition showed very little change (0:40–1:00 and 3:00–3:20). However, the Rh species were slowly but significantly oxidized under the stoichiometric condition that followed the rich condition (2:00–2:20 and 3:40–4:00). This suggests that the TWCR likely proceeds

on the surface Rh oxides and/or Rh species that are reduced by CO and/or C_3H_6 , even though the surface of the Rh species was oxidized after the lean condition. On the other hand, the almost completely metallic Rh surface under the rich condition is easily oxidized under the stoichiometric condition. These results suggest that both the metal-like and oxide-like Rh species display catalytic activity in CO and C_3H_6 oxidation and NO reduction, either individually or cooperatively. In this study, no information is available on the adsorbed species. Therefore, we have started to add a DRIFT apparatus to the *operando* system for this purpose.

The Fourier transform of the Rh *K*-edge EXAFS spectra of 1 wt% Rh/ Al_2O_3 during *operando* XAS measurement are shown in Figure 2. In the first period under the leanest condition, the decreases in the intensities of the Rh–Rh scattering peak at around 2.3 Å and the Rh–O peak at around 1.5 Å indicate oxidation of Rh species, which was initiated by exposure to the lean condition [(a), 0:00–0:20]. However, a small peak at around 2.3 Å remained under the oxidative atmosphere. This peak may indicate the remaining unoxidized Rh metallic cores. After the oxidation process, the Rh species showed little change by the end of the first stoichiometric condition [(b), 0:20–1:00]. This is completely consistent with the XANES temporal change. When the catalyst was exposed to the rich condition, the Rh species were abruptly reduced to the metallic state [(c), 1:00–1:25]. However, the Rh–O scattering peak at around 1.5 Å remained unchanged under the rich and second stoichiometric conditions [(d), 1:25–2:20]. This peak can be explained by the existence of remaining Rh_2O_3 cores and/or metal–support interactions at the Rh– Al_2O_3 interface. The introduction of a lean atmosphere again caused rapid [(e), 2:20–2:30] and then gradual oxidation [(f), 2:30–3:00] of Rh species. It is noteworthy that the Rh–O scattering peak at around 1.5 Å is relatively stable, but the Rh–Rh peak decreased significantly. This behavior is well correlated with the gradual increase in the amount of NO_x in the eluent gas (Figure 1, 2:20–2:30), the subsequent relatively stable detection of NO_x species (Figure 1, 2:30–3:00), and the corresponding temporal variation of the XANES spectra. We intended primarily to clarify the dynamic behavior of Rh species during the TWCR using XAS as a probe. However, from a different perspective, the reaction results observed using the micro GC, NO_x meter, and Q-Mass spectrometer are also probes for the Rh species. Thus, the increase in the amount of NO_x species (Figure 1, 2:20–2:30) determined using GC and XAS measurements, which are correlated with oxidation of the Rh species, indicates more precisely the oxidation of the *surface* Rh species. A kinetic approach toward understanding this behavior is discussed later. The third stoichiometric condition did not induce any significant changes in the Rh species [(g), 3:00–3:20], but the second rich condition again initiated rapid reduction of the Rh species [(h), 3:20–3:30]. The Rh species were stable by the end of the fourth stoichiometric condition [(i), 3:30–4:00] and oxidized under the last lean condition [(j), 4:00–4:20]. The complete profile of the Rh *K*-edge EXAFS spectra of 1 wt% Rh/ Al_2O_3 is provided in the Supporting Information (Figure S9).

4. DISCUSSION

4.1. Comprehensive interpretation in chronological order. The first lean condition (0:00–0:40) and the first stoichiometric condition (0:40–1:00) Before the feed gas was introduced, the XANES and EXAFS spectra at the very beginning

(Figures 1 and 2) suggest that the Rh species exist in a partially reduced state. It is evident from the GC profile (Figure 1) that the N_2 production at the second sampling point (0:03) was significantly larger than that at the following ones. This implies that the Rh species had a metallic surface, which would exhibit high catalytic activity in the NO reduction reaction but was instantly oxidized under the lean condition. The XANES and EXAFS spectra of the Rh species after the reaction did not show any remarkable change for successive 10 min. The apparent NO reduction activity abruptly changed within 3 min as the feed gas composition changed at 0:20 and 0:40. For example, in the NO_x profile, it is possible to identify an instant decrease in the detected NO_x species, which finished in about 2 min around 0:20. This point will be discussed in the next section. Under the first stoichiometric condition, the XANES and EXAFS spectra showed no change, but the N_2 production rate reached almost 100%, as expected. To summarize, the Rh species with a partially reduced surface were oxidized at the very beginning and remained unchanged in this period.

The first rich condition (1:00–2:00) and the second stoichiometric condition (2:00–2:20) As the atmosphere changed to the rich condition at 1:00, the Rh species were dramatically reduced to their metallic state. However, the NO reduction activity changed very little. This suggests that under rich conditions, the surface of the Rh species must be metallic, which suggests at least two different hypotheses on the structure of the Rh species. The first hypothesis is that the surface was already metallic under the first stoichiometric condition, but the inside of most of the Rh species was oxide-like; i.e., most of the Rh species existed as Rh_2O_3 with a thin Rh metallic layer, which was effective for NO reduction. This hypothesis is consistent with the XANES spectra and Fourier transforms of the EXAFS spectra observed at 1:00 and 1:25. Note that a small scattering peak at around 1.5 Å (Rh–O) was visible throughout the experiment. The second hypothesis is that the surface was nearly oxide-like at 1:00 and almost metallic at 1:25, but both Rh species were effective in catalyzing the reduction of NO under the present conditions. However, the drastic decrease of the NO reduction activity at the beginning of the reaction implies the importance of Rh surface state. We guess the second hypothesis is improbable under the present condition at this time, but we will examine this hypothesis in the near future. After 1:20, N_2 production was maintained at a nearly steady state, but CO_2 production decreased slightly, and remaining CO was also observed. It is impossible to interpret this phenomenon quantitatively and only in the framework of the TWCR. Therefore, the WGSr is considered to explain these observations, as described in the Supporting Information.

The second lean condition (2:20–3:00) and the third stoichiometric condition (3:00–3:20) Under the second lean condition, the Rh species were oxidized in two steps. The Fourier transforms of the EXAFS spectra at 2:20, 2:30, and 3:00 show a rapid increase in the intensity of the Rh–O peak and decrease in the intensity of the Rh–Rh peak in the first step. Subsequently, the intensity of the Rh–Rh peak decreases with a small change in the Rh–O peak. These observations imply that the Rh species were oxidized on the surface (the first step) and later in the bulk (the second step). An interesting phenomenon is observed in the GC and NO_x profiles, i.e., a relatively slow decrease in the production of N_2 (2:20–2:40). This point will be discussed later. Under the most oxidative atmosphere (2:40–3:00), the rate of N_2 production successively decreased to about 60%, which is slightly lower than the rate under the

first lean condition. We speculate that this is a result of a reduction in the specific surface area of the Rh species via the well-known aggregation process under rich conditions. When the atmosphere returned to the stoichiometric condition (3:00–3:20), the Rh species remained unchanged but exhibited good NO reduction catalytic activity. The activity in this period was the same as that under the first stoichiometric condition on the way from lean to rich conditions.

The second rich condition (3:20–3:40) and the fourth stoichiometric condition (3:40–4:00) After the feed gas was switched to the rich condition again, the Rh species were rapidly reduced to the metal-like state within 10 min. CO was detected in the Q-Mass spectrum, and H₂ gas was observed again. This indicates that the surface of the Rh species had been reduced and the WGSR had occurred, as in the first rich condition. The processes taking place under the fourth stoichiometric condition were the same as those under the second stoichiometric condition on the way from the rich to lean conditions, i.e., gradual surface oxidation of the Rh species. During this period, NO was quantitatively reduced to N₂.

The third lean condition (4:00–4:20) Under the final lean condition, the N₂ production rate gradually decreased to 60%, the same level as under the second lean condition. This implies that Rh agglomeration occurred only under the first rich condition and no longer occurred under the present condition. In addition, two different oxidation steps were observed, which can be interpreted as the surface oxidation process and the averaged oxidation state of Rh species.

4.2. Macro kinetics of the surface rearrangement of Rh species. As mentioned in the Results section, the NO_x profile at every gas composition change exhibited characteristic behavior. When the conditions changed from lean to less lean or stoichiometric ones at 0:20, 0:40, and 3:00, or from lean to more lean conditions at 2:40, the NO_x profile showed a discontinuous curve. However, when the conditions changed from stoichiometric to lean at the beginning (0:00), 2:20, and 4:00, the NO_x profile showed either continuous or sigmoidal curves, as shown in the Supporting Information (Figure S10). First, the discontinuous changes were observed 1 min and 15 s after the gas composition was switched. For example, the gas composition was changed at 0:20, and the discontinuous change was observed at around 0:21. Separately, we checked how long it took for the Q-Mass spectrometer to detect the gas switching. We found that it took about 1 min for the spectrometer to detect a switch in the inlet gas composition both with and without reaction conditions. This indicated that the delay of 1 min 15 s at the NO_x meter must have been due to the changes in the internal volume from the gas mixer to the detector. Thus, no induction period existed at each discontinuous change. On the other hand, the continuous behavior after the gas composition changes at 2:20 and 4:00 appeared completely different from the above behavior. The initial change was gradual and took about 10 min to complete. As the NO_x profile reflects the catalytic activity of NO reduction, it must be related to the properties of the catalytic sites, i.e., the surface Rh species. Thus, the NO_x profile can be regarded as an indicator of the oxidation ratio of surface Rh species. On the basis of this assumption, we tried to interpret the surface rearrangement of Rh species by borrowing an idea from phase transition or particle formation studies.

Kinetics of particle formation The mechanism of particle formation has been extensively studied in various fields relat-

ed to crystallography in every possible phase, namely, solid–solid, solid–liquid, and solid–gas. For example, the Johnson–Mehl–Avrami–Erofev equation, or, more simply, Avrami equation^{27–29} is a famous interpretation of particle formation in the solid-state reaction. On the other hand, the Finke–Watzky equations in either two steps³⁰ or four steps³¹ are common explanations of nanoparticle formation in the liquid phase. The relationship between the Avrami and Finke–Watzky equations has been extensively discussed by Finke et al. and Skrdla et al.^{32–34} If the NO_x concentration in the eluent gas is an indicator of the oxidation degree of the surface of the Rh species, it must be possible to apply the kinetic models discussed above to the NO_x profile.

Surface rearrangement of Rh species Figure 3 shows the (inverted) NO_x profiles and fitted curves in the important gas switching regions. The inverted NO_x profile plots the values as 1000 – NO_x (ppm). Basically, we assume that NO is reduced on the metal-like Rh site directly or indirectly. The reduction rate of NO can be assumed to be proportional to the number of metal-like Rh sites available for catalysis (i.e., on the surface). The inverted NO_x profile is the reduction rate of NO and must be proportional to the number of catalytically active metal-like Rh sites. Then, we hypothesize that the inverted NO_x profile can be proportional to the concentration of Rh⁰ species. The pseudo-first-order kinetic model (i.e., a simple exponential model, where [A]_t: concentration of Rh³⁺ at time *t*; [A]_d: difference between concentrations of Rh³⁺ in the initial and final states; *t*: time; *t*_{offset}: time offset; *τ*: time constant; [A]₁: offset of concentration of Rh³⁺ in the final states) was utilized to fit the inverted NO_x decay profiles [Figure 3(A), (B), (D), and (E)].

$$[A]_t = [A]_d \exp\left(-\frac{t - t_{\text{offset}}}{\tau}\right) + [A]_1$$

For Figure 3(A), (B), and (E), the oxide-like surface Rh species were exposed to richer gas. These results imply that the surface oxide-like (Rh₂O₃-like) Rh species was reduced randomly, and the reaction followed the pseudo-first-order kinetic model as a function of the concentration of the surface Rh₂O₃ species. The curve shown in Figure 3(D) similarly fitted this kinetic model. This indicates that metallic surface Rh species were oxidized randomly. On the other hand, it is obviously impossible to apply the pseudo-first-order kinetic model to the inverted NO_x profiles when the catalysts were exposed to lean gas conditions. Under these conditions, we applied the Finke–Watzky equation formulated from the two-step nanoparticle formation mechanism, as described below ([A]_t: concentration of Rh⁰ at time *t*; [A]₀: difference between concentrations of Rh⁰ in the initial and final states; [A]₁: offset of concentration of Rh⁰ in the final state; *t*: time; *k*₁: rate constant for Rh⁰ → Rh³⁺; *k*₂: rate constant for Rh⁰ + Rh³⁺ → 2Rh³⁺), and obtained well-fitted results [Figure 3(C) and (F)].

$$[A]_t = \frac{\frac{k_1}{k_2} + [A]_0}{1 + \frac{k_1}{k_2[A]_0} \exp((k_1 + k_2[A]_0)t)} + [A]_1$$

This implies that an oxide-like nucleus was first generated on the surface of the metallic Rh species under the lean condition (nuclear generation), and oxygen atoms were successively consumed around the oxide-like Rh species (autocatalytic reaction).

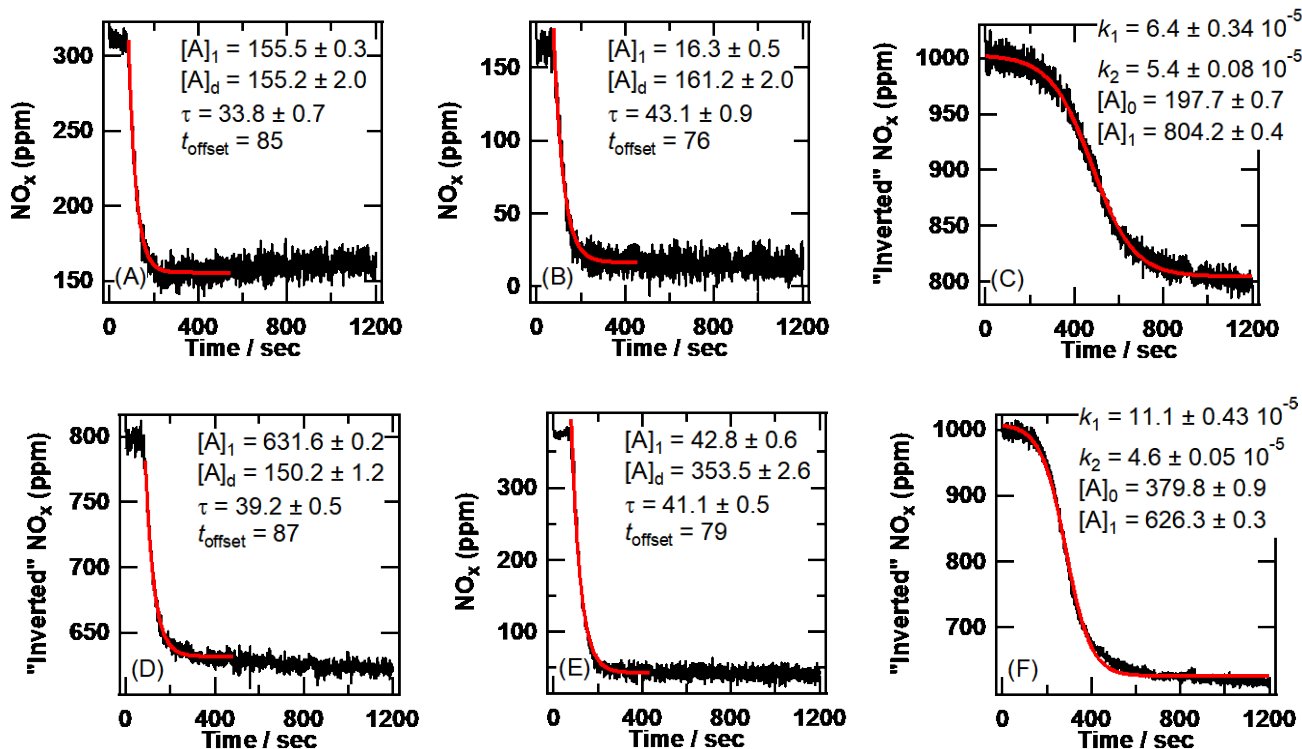

Figure 3. (Inverted) NO_x profiles with fitted curve based on pseudo-first-order kinetics or Finke–Watzky two-step particle formation mechanism in gas switching regions. (Red lines are fitted curves.) The time axis is defined as the elapsed time from (A) 0:20, (B) 0:40, (C) 2:20, (D) 2:40, (E) 3:00, and (F) 4:00.

After 600 s, the latter region exhibited a gradual decrease in the inverted NO_x profile. This behavior of the Rh_2O_3 -like species might be related to Ostwald ripening, which might be understood as a random walk of oxygen atoms on the surface of the Rh species. The combination of the two-step Finke–Watzky mechanism and the Ostwald ripening process has already been successfully applied to understand the formation mechanism of Ag or Pd nanoparticles in the liquid phase by Harada et al.³⁵⁻³⁶ However, this behavior has minimal significance in our case and can be simply ignored. It is important to note that there is a significant difference between the oxidation processes of a metallic surface and the reduction processes of an oxidized surface, as discussed above.

4.3. Schematic view of dynamic behavior of Rh species.

The dynamic behavior of Rh species when the gas composition is switched are summarized in Scheme 2. We assumed that the sizes of the Rh nanoparticles were almost unchanged because the intensities of the Fourier transforms of the EXAFS spectra at 1:25 (the first rich condition) and at 3:30 (the second rich condition) were similar. Considering the reduction process of Rh species, the surface of the oxide-like Rh species was easily reduced to the metallic state swiftly and randomly. On the other hand, in the oxidation process of Rh species, surface oxidation of Rh species proceeded via random and autocatalytic growth by oxide-like Rh site generation.

This schematic was deduced on the basis of examination of the outlet gas with a micro GC, a NO_x meter, and a Q-Mass spectrometer, and also from the results of the *operando* XAS study. Thus, this study demonstrates the importance of the surface state of Rh species during the TWCR. As real automobile exhaust contains many different gases such as H_2O , H_2 , various HCs, CO, CO_2 , NO, or NO_2 , the present observations

cannot be used to deduce the real TWCR conditions. However, this study provides clear insights that surface rearrangement of Rh can have a great impact on real TWCs, albeit on much smaller space and time scales.

5. CONCLUSION

In this study, an *operando* XAS measurement system equipped with a micro GC, NO_x meter, and Q-Mass spectrometer was successfully built at a public XAS beamline, BL01B1, at SPring-8. *Operando* spectroscopy itself is not new. However, most *operando* studies have used only one or two additional probes under conditions that differ significantly from typical laboratory conditions. In our work, four probes are fully integrated (XAS, micro-GC, NO_x meter, Q-Mass spectrometer), providing complementary data useful for gaining deep insight

into the nature of heterogeneous catalysts. Using this system, we directly observed the dynamic behavior of Rh species in 1 wt% Rh/Al₂O₃ under relatively idealized conditions. Consequently, we estimated the dynamics of surface and bulk Rh species during the TWCR by quantitative analysis obtained with various detectors *operando*. Of course, there are an enormous number of studies on the catalytic performance, mechanism, or degradation of TWCs that used various techniques independently. However, such studies have usually been performed under significantly different conditions, which sometimes made unified understanding difficult. In this study, we performed a catalytic performance test, investigated the catalytic mechanism in terms of surface chemistry, and even examined part of the degradation mechanism simultaneously. The present *operando* data obtained under the exactly same condition enables us to interpret them consistently, and this work is the first quantitative evaluation of surface rearrangement of Rh species using model automobile exhaust gases at the laboratory level. Although the present relatively idealistic condition was not so close to the real automobile exhaust condition, we believe this study sheds light on the fundamental dynamic behavior of Rh species in the Rh/Al₂O₃ catalyst under near-stoichiometric conditions.
