15

16 **Abstract**

17 The spatiotemporal relationship between granitoid intrusions and low-pressure/temperature type
18 regional metamorphism in the Ryoke belt (Mikawa area) is investigated to understand the tectono-
19 thermal evolution of the upper- to middle-crust during a Cretaceous flare-up event at the Eurasian
20 active continental margin. Three plutono-metamorphic stages are recognized; (1) 99–84 Ma:
21 intrusion of granitoids (99–95 Ma pulse) into the upper crust and high-*T* regional metamorphism
22 reaching sillimanite-grade (97.0 ± 4.4 Ma to 88.5 ± 2.5 Ma) in the middle crust, (2) 81–75 Ma:
23 intrusion of gneissose granitoids (81–75 Ma pulse) into the middle crust at ~19–24 km depth,
24 and (3) 75–69 Ma: voluminous intrusions of massive to weakly-foliated granitoids (75–69 Ma
25 pulse) at ~9–13 km depth and formation of contact metamorphic aureoles. Cooling of the highest-
26 grade metamorphic zone below the wet solidus of granitic rocks is estimated at 88.5 ± 2.5 Ma. At
27 ca. 75 Ma, the upper-middle crustal section underwent northward tilting, resulting in the
28 exhumation of regional metamorphic zones to ~9–13 km depth. Although the highest-grade
29 metamorphic rocks and the 99–95 Ma pulse granitoids preserve similar U-Pb zircon ages, the
30 absence of spatial association suggests that the regional metamorphic zones were mainly
31 produced by a transient thermal anomaly in the mantle and thermal conduction through the crust,
32 supplemented by localized advection due to granitoid intrusions. The successive emplacement of
33 granitoids into shallow, deep and shallow levels of the crust was probably controlled by the

34 combination of change in thermal structure of the crust and tectonics during granitoid intrusions.

39

40 1. Introduction

41 Continental arcs are extended belts where the production, upward migration, eventual
42 solidification at depth or eruption of magma contributes to form new continental material. Arcs
43 appear to be mainly built during periods of increased magma production ('flare-ups') punctuated
44 by stages of relatively lower magmatic activity ('lulls') (e.g. [Ducea, 2001](#)). Estimates of magma
45 addition rates in the Sierra Nevada Batholith (USA) indicate that 100–1000 times more magma
46 is added to continental arcs during flare-ups than during lulls, and that the ratio of plutonic to
47 volcanic material is about 30/1 ([Paterson and Ducea, 2015](#)). The latter ratio emphasizes the wealth
48 of information that can be gathered from relatively deep levels of eroded arc systems, where
49 plutonic rocks are widely exposed. This episodic nature of arc magmatism has a fractal character;
50 at a shorter (< 50 Ma) and smaller (< 50 km wide) scale, a 'flare-up' event involves discrete
51 'pulses' of increased magmatic activity (e.g. [de Silva et al., 2015](#)) while the depth of pluton
52 emplacement or the location of eruption centers varies with time ([Tibaldi et al., 2013](#); [de Saint
53 Blanquat et al., 2011](#)). Thus, understanding the origin and evolution of a flare-up event and its
54 associated crustal response requires deciphering its history in a shorter time-scale.

55 The Ryoke plutono-metamorphic belt, exposed in southwest to central Japan, is an
56 appropriate target to decipher the intricate history of a flare-up. First, it represents the upper- to
57 mid-crustal section of a continental arc in which voluminous I-type plutonic rocks (e.g. [Nakajima,](#)

58 [1994; Shibata and Ishihara, 1979a](#)) and thick ignimbrite sequences (e.g. [Yamada and Koido, 2005](#))
59 testify for the occurrence of a Cretaceous flare-up event ([Sato et al., 2016](#)). From a comprehensive
60 set of sensitive high resolution ion microprobe (SHRIMP) zircon dating results, [Tani et al. \(2014\)](#)
61 revealed that granite pulses in SW Japan occurred at 85, 60 and 35 Ma and were separated by 25
62 million year lulls. The flare-up event recorded in the Ryoke belt corresponds to the 85 Ma pulse.
63 Second, the Ryoke belt hosts low-pressure/temperature (low- P/T) type metamorphic rocks which
64 were variably affected by successive plutonic intrusions ([Brown, 1998; Ikeda, 1998a, b;](#)
65 [Kawakami, 2001; Kawakami and Suzuki, 2011; Miyake et al., 1992; Miyashiro, 1961; Miyazaki,](#)
66 [2010; Okudaira et al., 1993](#)). Thanks to the tectono-metamorphic record of these metasedimentary
67 rocks, constraints on the timing, depth and temperature of individual intrusions (e.g. [Endo and](#)
68 [Yamasaki, 2013; Miyake et al., 2016](#)) are much more accessible than for exclusively plutonic
69 regions.

70 The current challenge is to gather reliable time estimates of the magmatic activity and
71 metamorphic events in the Ryoke belt. For granitoids, the earliest geochronological results
72 involved whole-rock Rb–Sr ages and K–Ar or Rb–Sr ages on biotite and hornblende ([Kawano](#)
73 [and Ueda, 1967; Nozawa, 1975; Shibata and Ishihara, 1979b](#)), and their compilation revealed an
74 eastward younging from ca. 100 Ma to ca. 70 Ma over ~800 km ([Nakajima, 1994](#)). With the
75 assumption that these ages correspond to pluton solidification, the younging trend was explained

76 by a migration of magmatic activity due to the oblique subduction of the Kula-Pacific ridge
77 beneath the Eurasian continent (Nakajima, 1994; Kinoshita, 1995). However, chemical
78 Th–U–total Pb isochron method (CHIME) monazite ages subsequently obtained on high-grade
79 metamorphic rocks and granitoids turned out to be older than K–Ar biotite ages and were ascribed
80 to prograde metamorphism and pluton solidification, respectively (Suzuki et al., 1996; Suzuki and
81 Adachi, 1998). Following this view, the eastward younging of K–Ar biotite ages was ascribed to
82 a difference in the denudation rate rather than in magmatic activity, with the western part of the
83 belt having been eroded more rapidly than the eastern part (Suzuki and Adachi, 1998). More
84 recently, the growing number of available U–Pb zircon ages for the Ryoke granitoids revealed
85 discrepancies between U–Pb zircon, CHIME monazite and K–Ar biotite ages (Murakami et al.,
86 2006; Skrzypek et al., 2016; Takatsuka et al., 2018). The current tendency is to consider zircon as
87 the best tool to constrain the age of pluton solidification. The first advantage of zircon is its high
88 closure temperature near or above the solidus of granitic rocks. The second advantage is its
89 robustness with respect to secondary alteration/recrystallization compared to monazite and biotite
90 (e.g. Bosse et al., 2009; Kawakami et al., 2014). The third advantage is that it is the most
91 representative accessory mineral that can be dated in allanite-bearing granitoids where monazite
92 is virtually absent, as is the case for most granitoids in the Mikawa area so far (Takatsuka et al.,
93 2018).

94 In the present study, we aim to detail the spatial distribution and timing of plutonic
95 activity and regional metamorphism during the Cretaceous flare-up event which occurred at the
96 active continental margin of Eurasia. The solidification age of the so-called ‘Younger Ryoke’
97 granitoids exposed in the Mikawa area (Ryoke belt, central Japan) are newly determined using
98 U–Pb zircon dating by Laser Ablation Inductively Coupled Plasma Mass Spectrometry
99 (LA–ICP–MS). Additionally, the emplacement depth of several granitoids is estimated using Al-
100 in-hornblende barometry and published P – T estimates for the host metasedimentary rocks. The
101 timing of regional metamorphism is also constrained by LA–ICP–MS U–Pb zircon dating. The
102 results are combined to reconstruct how a former accretionary complex progressively transformed
103 to the granitoid-dominated, metamorphosed upper- to middle-crust of an arc during a flare-up
104 event.

105

106 **2. Geology of the Ryoke belt in the Mikawa area**

107 Within the Inner Zone of SW Japan, the Ryoke belt extends for about 800 km from northern
108 Kyushu to Tsukuba (Fig. 1a), and the Mikawa area is located in its eastern part. The Mikawa area
109 exposes low- P /high- T metamorphic rocks and voluminous granitic rocks (Fig. 1b; [Asami et al.,](#)
110 [1982; Miyake et al., 1992, 2014, 2016, 2017; Adachi and Wallis, 2008; Miyazaki, 2010; Takatsuka](#)
111 [et al., 2018](#)).

112 The Ryoke granitoids have been classically divided into the gneissose "Older Ryoke"
113 and massive "Younger Ryoke" granitoids based on lithology and intrusive relationships (Ryoke
114 Research Group, 1972). In the Mikawa area, the "Older Ryoke" granitoids include the Kamihara
115 tonalite, Tenryukyo granite and Kiyosaki granodiorite, whereas the "Younger Ryoke" granitoids
116 correspond to the Shinshiro tonalite, Mitsuhashi granodiorite, Inagawa granite and Busetsu
117 granite (Fig. 1b; Makimoto et al., 2004). All plutons are considered as I-type granitoids, except
118 for the Busetsu granite which has a composition close to that of S-type granites (Ishihara and
119 Chappell, 2007). CHIME monazite ages for the "Older Ryoke" and "Younger Ryoke" granitoids
120 are ca. 97–87 Ma and ca. 86–75 Ma, respectively (Table 1; Nakai and Suzuki, 1996; 2003;
121 Morishita et al., 1996; Morishita and Suzuki, 1995; Suzuki and Adachi, 1998; Suzuki et al., 1994a;
122 1994b; Miyake et al., 2016). Based on these CHIME monazite ages, the "Younger Ryoke"
123 granitoids were thought to have continuously intruded one after another from ca. 86 Ma to ca. 75
124 Ma (e.g., Suzuki and Adachi, 1998). Recently, however, LA-ICP-MS U-Pb zircon dating
125 revealed that the gneissose granitoids have a bimodal distribution of U-Pb zircon ages, with two
126 groups at ca. 99–95Ma and ca. 81–75 Ma, the latter age group being further divided into the
127 '81–75 Ma Hbl-Bt tonalite' and '78–75 Ma (Hbl)-Bt granite' (Fig. 1b; Takatsuka et al., 2018).
128 In contrast to the U-Pb zircon and CHIME monazite ages, K-Ar ages of biotite and hornblende
129 from the "Older Ryoke" and "Younger Ryoke" granitoids show similar values of ca. 73–66 Ma

130 (Table 1).

131 The metamorphic rocks represent equivalents of the Jurassic to Early Cretaceous
132 accretionary complex material which is found in the northerly Mino-Tanba belt (Wakita, 1987).
133 They are composed of metachert, metasandstone and metamudstone with scarce metabasalt
134 (Makimoto et al., 2004). The metamorphic rocks are foliated, strike NE–SW to E–W and variably
135 dip towards the north. In the south of the study area, both north- and south-dipping foliation planes
136 are observed and point to km-scale upright folding. Three regional metamorphic zones and one
137 contact metamorphic zone are defined in the Mikawa area; the former are the Bt, Kfs–Sil and
138 Grt–Crd zones in order of increasing metamorphic grade (Fig. 1b; Makimoto et al., 2004;
139 Miyazaki et al., 2008; Nakashima et al., 2008; Yamasaki and Ozaki, 2012). The peak P – T
140 conditions of each metamorphic zone are estimated to be 0.29–0.37 GPa, 506–593 °C for the Bt
141 zone, 0.37–0.43 GPa, 574–709 °C for the Kfs–Sil zone, and 0.43–0.57 GPa, 715–801 °C for the
142 Grt–Crd zone (Miyazaki, 2010). The contact metamorphic zone (Kfs–Crd zone) is developed
143 around the "Younger Ryoke" granitoids (Endo and Yamasaki, 2013; Miyazaki et al., 2008;
144 Yamasaki and Ozaki, 2012); its P – T conditions are 0.23–0.24 GPa and > 600 °C around the
145 Shinshiro tonalite and the Mitsuhashi granodiorite (Endo and Yamasaki, 2013), and 0.32 GPa and
146 > 630 °C around the Inagawa granite (Miyake et al., 2016).

147 Pelitic and psammitic gneiss samples from the Kfs–Crd zone give CHIME monazite

148 ages of ca. 102–98 Ma which are interpreted as the timing of prograde monazite growth at upper
149 amphibolite facies conditions during regional metamorphism (Suzuki et al., 1994a, b). K–Ar
150 biotite ages of ca. 67.5 Ma and ca. 69 Ma are reported for a Bt schist sample (Kfs–Crd zone)
151 nearby the Kiyosaki granodiorite (Ueno et al., 1969). SHRIMP U–Pb zircon ages of ca. 87 Ma
152 are reported for a migmatite sample from the Grt–Crd zone and are correlated with the timing of
153 peak regional metamorphism (Nakajima et al., 2013). Among mafic igneous rocks sporadically
154 exposed in the Mikawa area (Fig. 1b), hornblende gabbro and basaltic andesite give SHRIMP
155 U–Pb zircon ages of 72.4 ± 1.2 Ma and 71.5 ± 1.1 Ma, respectively (Nakajima et al., 2004).

156

157 **3. Analytical procedures**

158 Quantitative analyses of hornblende were performed using a JEOL JXA-8105 superprobe at
159 Kyoto University. Analytical conditions were an acceleration voltage of 15.0 kV, a beam current
160 of 10 nA and a beam diameter of 3 μ m. The counting time for the peak and backgrounds were 30
161 s and 15 s for Cl, 60 s and 30 s for F, and 10 s and 5 s for other elements. Natural and synthetic
162 minerals were used as standards and ZAF correction was applied.

163 Granitoid, leucosome (GY03D) and pegmatite (GY47A) samples were crushed using
164 Selfrag Lab at the National Institute of Polar Research (NIPR), Japan. Zircon grains were
165 separated by panning, handpicking under a stereomicroscope, and were mounted in epoxy.

166 Cathodoluminescence (CL) and backscattered electron (BSE) images were obtained using a JEOL
167 JXA-8105 superprobe at Kyoto University. Inclusions in zircon were identified using a S3500H
168 scanning electron microscope equipped with an EDAX X-ray analytical system, and Al_2SiO_5
169 minerals were identified by Raman spectroscopy (JASCO NRS 3100) at Kyoto University.

170 U–Pb zircon dating by LA–ICP–MS was performed in Kyoto University and
171 Gakushuin University. Most analyses were done on separated zircon grains. Dating in Kyoto
172 University was performed using a Nu PlasmaII multi-collector ICP–MS coupled to a NWR193
173 laser-ablation system utilizing a 193 nm ArF excimer laser. Dating in Gakushuin University was
174 performed using an Agilent8800 single-collector ICP–MS coupled to a NWR213 laser-ablation
175 system utilizing a 213 nm Nd:YAG laser. The 91500 zircon (Wiedenbeck et al., 1995, 2004) was
176 used as a primary reference material for Pb/U and Th/U ratios while NIST SRM610 glass (Pearce
177 et al., 1997; Jochum and Brueckner, 2008) was used for Pb/Pb isotope ratios. Details on the
178 analytical procedures and data reduction schemes are summarized in Supplementary material
179 (Table S1). Secondary standard analyses indicate that inter-laboratory differences in zircon dating
180 results are not significant (Takatsuka et al., 2018). Isoplot 4.15 (Ludwig, 2012) was used to
181 construct concordia diagrams and to calculate weighted mean $^{206}\text{Pb}/^{238}\text{U}$ ages. Analyses with
182 concordance $[\text{=} (^{206}\text{Pb}/^{238}\text{U} \text{ age}) * 100 / (^{207}\text{Pb}/^{235}\text{U} \text{ age})]$ between 97 and 103% are referred to as
183 concordant in this study and used for calculating weighted mean $^{206}\text{Pb}/^{238}\text{U}$ ages.

184

185 **4. Sample description**

186 **4.1. Shinshiro tonalite**

187 Samples GY50A [N34.914783°, E137.455796°] and GY100A [N34.940262°, E137.548428°] are
188 Hbl-Bt tonalites (Fig. 1), both corresponding to the main facies of the Shinshiro tonalite (Ohtomo,
189 1985). On the outcrops, a moderate foliation defined by the arrangement of biotite and hornblende
190 can be recognized, and ellipsoidal mafic enclaves with their long axis oriented parallel to the
191 foliation are present (Fig. 2a, b). This foliation has been interpreted to be magmatic in origin
192 (Ohtomo, 1985). Both samples are composed of Qtz, Pl, Kfs, Bt and Hbl with accessory Ap, Zrn,
193 Ilm, Ttn, secondary Ep and secondary Chl (Fig. 3a, b). Allanite is present in sample GY100A.

194 **4.2. Mitsuhashi granodiorite**

195 Sample GY99A [N35.047113°, E137.523850°] is a Hbl-Bt granodiorite (Fig. 1) with a weak
196 foliation defined by the arrangement of biotite and hornblende (Fig. 2c). The granodiorite is
197 composed of Qtz, Pl, Kfs, Bt and Hbl with accessory Ap, Zrn, Ilm, Ttn and secondary Chl (Fig.
198 3c).

199 **4.3. Inagawa granite**

200 Samples GY86A [N35.057774°, E137.256294°] and GY93A [N35.149147°, E137.301422°] are
201 Hbl-Bt granites with Kfs megacrysts clearly showing the Carlsbad twin (Fig. 1). Sample GY86A

202 collected from the ‘gneissose porphyritic facies’ (Yamasaki and Ozaki, 2013) shows a weak
203 foliation defined by the arrangement of biotite, whereas sample GY93A collected from the
204 ‘massive facies’ (Yamasaki and Ozaki, 2013) shows a faint grain-shape preferred orientation of
205 Kfs megacrysts and amphibole (Fig. 2d, e). Both samples are composed of Qtz, Pl, Kfs, Bt and
206 Hbl with accessory Ap, Aln, Zrn, Ilm and Ttn (Fig. 3d, e). Xenomorphic Ep is present as a matrix
207 mineral, filling intergranular spaces between euhedral plagioclase grains together with secondary
208 Chl in sample GY93A, whereas secondary Ep overgrowing rims of allanite, secondary Py, and Po
209 included in Kfs are present in sample GY86A.

210 **4.4. Busetsu granite**

211 Samples GY51A [N34.967778°, E137.335781°] and MK02M [N34.954766°, E137.326847°] are
212 Grt-bearing two-mica granites and sample GY89A [N35.030050°, E137.296534°] is a two-mica
213 granite (Fig. 1). At locality GY51, biotite-rich lenses and pelitic xenoliths (2–4 cm in length)
214 locally occur within the medium-grained granite (Fig. 2f). Sample MK02M was collected 1 m
215 away from the discordant contact between fine-grained granite and Grt-bearing biotite
216 metapsammite; the Busetsu granite obliquely cuts the subvertical bedding in metapsammite there
217 (Fig. 2g). Sample GY89A was collected close to the N–S trending contact with the western edge
218 of the Kamihara tonalite (Fig. 1). The arrangement of Bt, Ms, and Qtz ribbons define a moderate
219 mylonitic foliation (N 152°/65° SW) which surrounds the Kfs megacrysts (Fig. 2h). Bulging

220 recrystallization of quartz indicates low-*T* deformation during the possible fault-like reactivation
221 of the former contact. All samples of the Busetsu granite are composed of Qtz, Pl, Kfs, Bt and Ms,
222 and samples MK02M and GY51A additionally contain Grt (Fig. 3f–h). Accessory Ap, Mnz, Zrn,
223 Ilm and xenotime are present in all samples.

224 **4.5. Metasedimentary rocks between the Kamihara and Busetsu granitoids**

225 A narrow band (< 1 km wide on map view) of metamorphic rocks occurs between the southern
226 edge of the Kamihara tonalite and the Busetsu granite (Fig. 1). At several localities, psammitic
227 gneiss with an E–W striking and N-dipping foliation is locally intruded by concordant sills of
228 fine- to medium-grained granite containing Bt, Ms and Grt. At locality GY92, a pelitic gneiss
229 sample (GY92A1) consists of And, Sil (postdating And), Crd (replacing And rims), Bt, Kfs, Pl,
230 Qtz, secondary Ms, and subordinate Tur, Ap, Mnz, Zrn and Gr. Andalusite has a chiastolite texture
231 and is partly transformed to prismatic sillimanite or fibrolite at the rim (Fig. 3i). Inclusion minerals
232 defining the chiastolite texture does not define an internal foliation (cf. Adachi and Wallis, 2008).
233 Andalusite is surrounded by and replaced by pinitized cordierite at the rim. The main foliation
234 defined by the arrangement of biotite and fibrolite is deflected around the andalusite
235 porphyroblasts, which indicates a pre-tectonic growth of andalusite and cordierite (Fig. 3i).
236 Secondary muscovite grains replace fibrolite and some of them discordantly cut the foliation.

237 **4.6. Migmatite and pegmatite from the Grt-Crd zone**

238 A ~20 cm thick leucosome in a psammitic metatexite migmatite (GY03D) and a pegmatite
239 concordant with migmatitic banding (GY47A) were collected from the Grt–Crd zone (Fig. 1).
240 The leucosome in sample GY03D is subparallel to the migmatitic banding of the host psammitic
241 migmatite (Fig. 2i), and mainly consists of Bt, Ms, Grt, Kfs, Pl and Qtz, with accessory Tur, Ap,
242 Zrn and opaque mineral (Fig. 3k). Myrmekite is common. The pegmatite concordant with the
243 migmatitic banding (GY47A) is found as a layer (~30–40 cm thick) below mafic lenses enclosed
244 in metatexite migmatite (Fig. 2j). The same cm-thick pegmatite also rims the structurally upper
245 side of the mafic lenses, and is further surrounded by the gneissose structure of the metatexite
246 migmatite hosting them. The pegmatite mainly consists of Kfs, Qtz, Pl, Bt, Crd, Sil, and Ms, with
247 accessory Ap, Zrn and Mnz. Fine-grained myrmekite is abundant along the grain boundaries of
248 K-feldspar, where sillimanite and secondary muscovite are common (Fig. 3l). The rims of quartz
249 grains are locally recrystallized into finer grains (Fig. 3l).

250

251 **5. U–Pb zircon dating**

252 Cathodoluminescence images of representative zircon grains from all granitoid samples are
253 presented in Figures 5 and 6, and those from migmatite and pegmatite samples are presented in
254 Figures 7 and 8. The weighted mean ages and spot ages reported below are $^{206}\text{Pb}/^{238}\text{U}$ ages unless
255 specified.

256 **5.1. Shinshiro tonalite**

257 Most zircon grains from samples GY50A and GY100A have homogeneous or oscillatory-zoned
258 cores, overgrown by oscillatory-zoned CL-bright rims (Fig. 4a, b, e, f).

259 *Sample GY50A*

260 A total of 61 spots on 23 grains was analyzed (Table S2; spots 1.1–2.11 and 12.1–14.13). Two
261 data were rejected because of irregular signals. One grain has an inherited core with a concordant
262 age of 1880 ± 37 Ma ($^{207}\text{Pb}/^{206}\text{Pb}$ age). Concordant analyses of Cretaceous domains have
263 $^{206}\text{Pb}/^{238}\text{U}$ ages ranging from ca. 79 to ca. 68 Ma. Two grains with CL-dark oscillatory zoning
264 (Fig. 4c, d) yield ca. 79–76 Ma and are slightly older than the other Cretaceous concordant ages
265 (ca. 71–68 Ma). The main age population is well defined at ca. 71–68 Ma, and its weighted mean
266 is 69.5 ± 0.3 Ma (32 spots, MSWD = 1.07, Fig. 8a).

267 *Sample GY100A*

268 A total of 33 spots on 14 grains was analyzed (Table S2; spots 71.7–73.13). One data was rejected
269 because of irregular signal. The $^{206}\text{Pb}/^{238}\text{U}$ ages of all Cretaceous concordant data range from ca.
270 73 to ca. 69 Ma, and their weighted mean is 70.6 ± 1.0 Ma (9 spots, MSWD = 0.44, Fig. 8b).

271 **5.2. Mitsuhashi granodiorite**

272 Zircon grains from sample GY99A have homogeneous or oscillatory-zoned cores overgrown by
273 oscillatory-zoned rims (Fig. 4g–h). A total of 32 spots on 15 grains was analyzed (Table S2; spots

274 69.1–71.6). One data point was rejected because of irregular signal. One grain has an inherited
275 core with a concordant age of 501 ± 18 Ma. The $^{206}\text{Pb}/^{238}\text{U}$ ages of all Cretaceous concordant data
276 range from ca. 76 to ca. 71 Ma and define a single age population (Fig. 8c). Their weighted mean
277 is 73.2 ± 0.7 Ma (11 spots, MSWD = 0.91, Fig. 8c).

278 **5.3. Inagawa granite**

279 Zircon grains from samples GY86A and GY93A show homogeneous or oscillatory-zoned cores
280 and oscillatory-zoned rims (Fig. 4i–l).

281 *Sample GY86A (gneissose porphyritic facies)*

282 A total of 39 spots on 17 grains was analyzed (Table S2; spots 33.1–35.13) and 25 analyses are
283 concordant. One grain has an inherited core with a concordant age of 296 ± 13 Ma. The $^{206}\text{Pb}/^{238}\text{U}$
284 ages of all Cretaceous concordant data range from ca. 78 to ca. 72 Ma, and show a single age
285 population. Their weighted mean is 74.7 ± 0.7 Ma (24 spots, MSWD = 0.61, Fig. 8d).

286 *Sample GY93A (massive facies)*

287 A total of 33 spots on 15 grains was analyzed (Table S2; spots 64.1–66.7), and 16 analyses are
288 concordant. The $^{206}\text{Pb}/^{238}\text{U}$ ages of all concordant data range from ca. 72 to ca. 68 Ma, and show
289 a single population. Their weighted mean is 69.2 ± 0.5 Ma (16 spots, MSWD = 1.02, Fig. 8e).

290

291 **5.4. Busetsu granite**

292 Zircon grains in Busetsu granite samples record four Cretaceous growth stages at (A) ca. 99 Ma,
293 (B) ca. 95–84 Ma, (C) ca. 80 Ma and (D) ca. 70 Ma (Figs. 5; 8f–h). These age domains are
294 associated with particular textural and compositional features. Domain A corresponds to
295 oscillatory- or sector-zoned cores and rims with a relatively high Th/U ratio (0.34–0.52) and a ca.
296 99 Ma age (Fig. 5a); only one grain of this type has been found so far. Domain B corresponds to
297 the homogeneous to weakly oscillatory-zoned parts commonly occurring in zircon mantle (i.e.
298 between core and rim). These mantles include sillimanite needles, have a low Th/U ratio
299 (0.02–0.12) and ages of ca. 95–85 Ma (Fig. 5b–g). Domain C corresponds to mantle or rim parts
300 with a homogeneously bright or oscillatory-zoned CL pattern, a moderate Th/U ratio (0.22–0.44,
301 with one exception at 0.04) and a ca. 80 Ma age (Fig. 5e–i). Domain D correspond to sector- or
302 oscillatory-zoned cores and oscillatory-zoned rims with a variable Th/U ratio (0.06–2.38) and a
303 ca. 70 Ma age (70.8 ± 1.4 Ma to 69.5 ± 0.4 Ma; Fig. 5b–d, h–m). Domain D is dominant in all
304 three samples.

305 *Sample GY51A*

306 A total of 112 spots on 45 grains was analyzed (Table S2; spots 4.11–6.13, 15.1–20.13 and
307 63.5–63.9), and 51 analyses gave concordant data. Nine data were rejected because of irregular
308 signals. The weighted mean age of domain D analyses (cores and rims) is 69.5 ± 0.4 Ma (37 spots,
309 MSWD = 2.3, Fig. 8f). Some cores give concordant, inherited ages of 1896 ± 38 Ma and $2272 \pm$

310 35 Ma ($^{207}\text{Pb}/^{206}\text{Pb}$ age). Zircon grains showing domain B \pm domain C + domain D around some
311 inherited cores (Fig. 5b–c; 4 grains) give a concordant age of 254 ± 6 Ma for the inherited core
312 and ca. 95–91 Ma for domain B mantles with a low Th/U ratio (0.02–0.12). Zircon grains with
313 domain B + domain C (3 grains) give concordant ages of ca. 86–84 Ma and ca. 80–78 Ma for
314 domain B (low Th/U ratio, 0.06–0.09) and domain C, respectively (Fig. 5e–g). Oscillatory-zoned
315 rims were not analyzed because they are thinner than the laser spot size. Zircon grains with
316 domain C + domain D (2 grains) give discordant dates of ca. 78–77 Ma for both cores and mantles.

317 *Sample MK02M*

318 A total of 26 spots on 15 grains was analyzed (Table S2; spots 44.1–45.13). One data was rejected
319 because of irregular signal. Domain D yields concordant ages of ca. 75–68 Ma, and the weighted
320 mean ages is 70.9 ± 0.9 Ma (21 spots, MSWD = 1.5, Fig. 8g). An inherited core with a discordant
321 date of ca. 1960 Ma ($^{207}\text{Pb}/^{206}\text{Pb}$) is also observed. In one grain preserving an inherited core \pm
322 domain B \pm domain C + domain D, the mantle part (B) gives a concordant age of 89.4 ± 4.0 Ma
323 with a Th/U ratio of 0.03 (Fig. 5d). Zircon grains with domain C + domain D (2 grains) gave
324 concordant ages of ca. 79–77 Ma for core or mantle parts (Fig. 5h, i).

325 *Sample GY89A*

326 A total of 26 spots on 13 grains was analyzed (Table S2; spots 46.1–47.13). Four data were
327 rejected because of irregular signals. Except for one grain, all analyzed domains are classified

328 into domain D. Zircon grains with domain D cores and rims yield concordant ages of ca. 74–68
329 Ma, and the weighted mean age is 70.8 ± 1.4 Ma (11 spots, MSWD = 1.6, Fig. 8h). Inherited cores
330 with concordant ages of ca. 270–191 Ma and ca. 1905–1879 Ma ($^{207}\text{Pb}/^{206}\text{Pb}$ age) are also
331 observed. The outermost rim of one oscillatory-zoned zircon yields a concordant age of $96.6 \pm$
332 4.3 Ma (Fig. 5a) and is tentatively classified as domain A.

333 **5.5. Migmatite and pegmatite from the Grt-Crd zone**

334 *Sample GY03D (~20 cm thick leucosome in metatexite)*

335 Zircon grains commonly show CL-bright cores and CL-dark rims (Fig. 6). Rims are composed of
336 CL-bright inner rims and CL-dark outer rims, and a CL-dark annulus (e.g. Kawakami et al., 2013)
337 is commonly observed between the cores and the inner rims. Sillimanite is found as inclusions in
338 the inner rim (Fig. 6) of two zircon grains. A total of 39 spots on 18 grains was analyzed (Table
339 S2; spots 41.1–43.13). Four data were rejected because of mixed analysis between cores and rims,
340 and one data was rejected because of irregular signal. Zircon cores give various inherited ages
341 (Table S2). Rims give scattered concordant ages from ca. 103 Ma to ca. 83 Ma (Fig. 9a, b). Inner
342 rims have a low U concentration (< 1300 ppm) and various Th/U ratio whereas outer rims are U-
343 richer (> 2300 ppm) and show very low Th/U ratio (Fig. 9c, d). The inner rims tend to give older
344 ages ranging from ca. 101 Ma to ca. 92 Ma (weighted mean; 97.0 ± 4.4 Ma, 6 spots, MSWD =
345 3.8). In contrast, the outer rims tend to give younger ages from ca. 95 Ma to ca. 83 Ma (weighted

346 mean; 88.5 ± 2.5 Ma, 12 spots, MSWD = 4.1) (Figs. 6, 9c, d). There was no tendency for U-rich
347 zircon domains to give older ages (cf. Skrzypek et al., 2016).

348 *SampleGY47A (Pegmatite)*

349 Zircon grains commonly show oscillatory-zoned cores and CL-dark rims (Fig. 7). Sillimanite is
350 found as an inclusion in the rim (Fig. 7). A total of 19 spots on 5 grains was analyzed (Table S2;
351 spots 9.1–9.13, 27.8–27.13). Two data were rejected because of mixed analysis between cores
352 and rims. Zircon cores give various inherited ages (Fig. 7; Table S2). Rims give relatively
353 clustered concordant ages from ca. 93 Ma to ca. 87 Ma with one outlier of ca. 98 Ma spot (Figs.
354 7, 9e, f). The concordia age for the zircon rims in this sample gave 90.1 ± 1.2 Ma (8 spots, MSWD
355 = 4.2), excluding the ca. 98 Ma outlier (Fig. 9e–f).

356 **6. Al-in-hornblende geobarometry**

357 In order to estimate the crystallization depth of the ‘81–75 Ma Hbl–Bt tonalite’ and ‘78–75 Ma
358 (Hbl)–Bt granite’, which are the gneissose granitoids thought to postdate regional metamorphism
359 (Takatsuka et al., 2018), the Al-in-hornblende geobarometer (Schmidt, 1992) was applied to
360 samples GY33A and GY81B (Fig. 1). Sample GY33A is a Hbl-Bt granite (Goyu area) while
361 sample GY81B is a Hbl-Bt tonalite (Hazu area). Their respective U–Pb zircon ages are 78 ± 1 Ma
362 and 81 ± 1 Ma, and their full description is given in Takatsuka et al. (2018). In both granitoids,
363 the mineral assemblage Hbl + Bt + Pl + Kfs + Qtz + Ap + Ilm + Ep + Ttn (+ Po + Py + Zrn)

364 permits the application of the geobarometer. Representative WDS analyses of hornblende used in
365 the estimates are given in Tables S3 and S4. The total Al content was calculated based on O = 23,
366 assuming total iron as Fe²⁺.

367 Hornblende grains in sample GY33A are in contact with Qtz, Pl, Kfs and Bt, and are
368 partially retrogressed to Bt and Chl at the rims or along cracks. Hornblende grains in sample
369 GY81B are in contact with Qtz, Pl and Bt, and compositional zoning is observed under the optical
370 microscope while it is not noticeable in BSE images. The total Al in hornblende ranges from 0.89
371 to 2.13 atoms per formula unit (a.p.f.u.) for sample GY33A, and from 1.66 to 2.30 a.p.f.u. for
372 sample GY81B. Low-Al domains present along the cracks in hornblende (sample GY33A) and
373 the local development of high-Al domains at the rims of hornblende (both samples) are considered
374 as secondary features which do not record the timing of granitoid crystallization. Excluding these
375 domains, the total Al content of hornblende in both samples is 1.70–2.00 a.p.f.u. for the rims (O
376 = 23, Tables S3 and S4). For geobarometry, the total Al content of hornblende rims was used
377 because rims are considered to have equilibrated with the final melt, fluid and other coexisting
378 minerals at the granitic wet solidus. With the calibration of [Schmidt \(1992\)](#), pressure estimates
379 are 0.50–0.64 GPa and 0.50–0.63 GPa for samples GY33A and GY81B, respectively.
380 Geobarometry was not applied to the Kamihara tonalite and Kiyosaki granodiorite samples
381 because appropriate mineral assemblage was not found.

382

383 **7. Regional implications**

384 **7.1. Interpretation of U–Pb zircon dating results**

385 In the Shinshiro tonalite and Mitsuhashi granodiorite samples, zircon is found included in major
386 minerals or along grain boundaries (Fig. 3a–c), and the majority of zircon shows a CL-bright
387 oscillatory zoning pattern (Fig. 4a–h). These magmatic features suggest that the dominant age
388 population of each sample reflects the timing of magma crystallization, which occurred at ca. 70
389 Ma for the Shinshiro pluton and ca. 73 Ma for the Mitsuhashi pluton. The main facies of the
390 Shinshiro pluton dated in this study and of Mitsuhashi pluton locally hosts allanite (Yamasaki and
391 Ozaki, 2012) and virtually does not contain monazite. Therefore, monazite-bearing granitoid
392 samples used for CHIME monazite dating that yielded 84–86 Ma ages (Suzuki et al., 1994a, b;
393 Morishita and Suzuki, 1995) do not correspond to the typical facies of each pluton, and a strong
394 interaction with the surrounding metamorphic rocks is inferred. These older monazite grains may
395 be derived from the neighboring metamorphic rocks in which the age of high-*T* regional
396 metamorphism was estimated at ca. 97–89 Ma based on U–Pb zircon dating in this study (see
397 below). Similarly, the CL-dark 77 Ma zircon grains found in the Shinshiro tonalite (Fig. 4c, d)
398 could be derived from the neighboring '78–75 Ma (Hbl)–Bt granite' (sample GY48D in Takatsuka
399 et al., 2018).

400 In the Inagawa pluton, zircon analyses define a dominant population at 74.7 ± 0.7 Ma
401 for the gneissose porphyritic facies and 69.2 ± 0.5 Ma for the massive facies (Table 2). The
402 ubiquitous occurrence of oscillatory-zoned zircon in both samples is used to ascribe these results
403 to magma solidification. The age of the gneissose porphyritic facies is consistent with the U–Pb
404 zircon age of 73 ± 3 Ma reported from a similar lithology within the Asuke Shear Zone (Murakami
405 et al. 2006; Fig. 8). Again, the absence of monazite and presence of euhedral magmatic allanite
406 in both samples suggests that the previously reported CHIME ages (83–82 Ma; Suzuki and Adachi,
407 1998) are probably not related to the crystallization of the main magma batch.

408 Zircon ages of the metatexite migmatite and pegmatite samples from the Grt-Crd zone
409 place important constraints on the timing of regional metamorphism in the Mikawa area. Zircon
410 grains from the metatexite leucosome GY03D show two stages of rim growth that are texturally,
411 chemically and chronologically distinct; CL-bright, low-U inner rims with a weighted mean age
412 of 97.0 ± 4.4 Ma are overgrown by CL-dark, high-U outer rims with a weighted mean age of 88.5
413 ± 2.5 Ma (Figs. 6, 9a–d). The high MSWDs of these weighted mean ages might be due to a
414 continuous growth of zircon rims from 102.9 ± 4.6 Ma to 83.1 ± 3.7 Ma (Figs. 6, 9a–d), but this
415 requires confirmation by higher precision age dating. In the present study, we attach importance
416 to the fact that zircon rims texturally record two growth stages and consider the weighted mean
417 ages as their growth timings. There are two possible scenarios for the origin of inner rims. First,

418 the inner rims might be resulted from prograde growth due to Ostwald ripening in the presence
419 of melt as proposed in another part of the Ryoke belt (Kawakami et al., 2013). In the present study,
420 the variable Th/U ratios (0.01–0.11) observed for the inner rims of zircon, compared to nearly
421 constant values for the outer rims (Fig. 9d), may reflect the chemical variation of fine-grained
422 detrital zircon grains consumed by the Ostwald ripening process which probably took place in
423 isolated melt pockets with different local compositions. Variable Th/U ratio of zircon cores
424 (0.04–1.45) is consistent with this interpretation (sample GY03D in Table S2). Alternatively, the
425 inner rims may reflect early zircon crystallization from melt at the very beginning of the cooling
426 stage immediately after the temperature peak. The entrapment of sillimanite might have equally
427 occurred during prograde or retrograde zircon growth at hypersolidus conditions. In this study,
428 the former interpretation that the inner rims represent the prograde growth of zircon is preferred
429 based on the observation of Th/U ratios. In both cases, the outer rim age of 88.5 ± 2.5 Ma is
430 interpreted as the timing of final zircon crystallization from melt at the granite wet solidus, and a
431 *P-T* path with a single temperature peak is sufficient to account for the inferred zircon
432 crystallization history (e.g., Brown, 1998; Kawakami et al., 2001). The pegmatite sample GY47A
433 contains cordierite and sillimanite, and could be a segregated partial melt derived from the
434 surrounding or underlying migmatites. The concordia age of 90.1 ± 1.2 Ma (Fig. 9e) represents
435 the timing of zircon crystallization in the pegmatite in the sillimanite stability field (Fig. 7), and

436 probably approximates the crystallization timing of the pegmatite melt. Judging from the
437 available data above, the hypersolidus stage of Ryoke regional metamorphism in the Mikawa area
438 started at 97.0 ± 4.4 Ma and continued until 88.5 ± 2.5 Ma.

439 In all samples from the Busetsu granite, zircon analyses reveal the presence of several
440 age domains. Domain A was recognized in only one zircon from a Grt-free granite sample
441 (GY89A) collected next to the western edge of the Kamihara pluton (Fig. 1). This grain shows a
442 texture, age and Th/U ratio similar to those of zircon grains from the Kamihara tonalite (see
443 [Takatsuka et al., 2018](#)), suggesting that it is a xenocryst derived from the neighboring pluton (Fig.
444 1). Domain B preserves homogeneous zoning and low Th/U ratios which are typical for
445 metamorphic zircon (e.g. [Rubatto, 2002](#)). Furthermore, a few sillimanite grains are found as
446 inclusions in this domain. Their age of ca. 95–85 Ma is in agreement with that of high-*T* regional
447 metamorphism in the Grt–Crd zone (Fig. 9). Therefore, zircon grains with domain B were likely
448 introduced into the Busetsu granite magma as xenocrysts originating from the assimilated
449 metamorphic rocks that existed in the source region or along the intrusion pathway of the granite.
450 The age of domain C (ca. 80 Ma) coincides with that of gneissose granitoids from the southern
451 part of the Mikawa area ('81–75 Ma Hbl–Bt tonalite'; [Takatsuka et al., 2018](#)). Considering the
452 moderate Th/U ratio of these domains, zircon grains with domain C alone could be considered as
453 xenocrysts derived from the assimilated gneissose granitoids, but the coexistence of domains B

454 and C in some grains points to a more complex history. Domain D are by far the most voluminous
455 (Fig. 5); their sector or oscillatory zoning pattern and relatively high Th/U ratio indicate that they
456 record a major event of magma crystallization which is ascribed to the solidification of the
457 Busetsu granite at ca. 70 Ma. It is worth noting that for the Busetsu granite, in which monazite is
458 a common accessory mineral while allanite is not observed, CHIME monazite ages ($79-75 \pm 5$
459 Ma; [Suzuki et al., 1994](#); [Nakai and Suzuki, 2003](#)) are nearly compatible with U-Pb zircon ages
460 ($71-69 \pm 1$ Ma).

461

462 **7.2. Timing and depth distribution of granitoid intrusions in the Mikawa area**

463 The U–Pb zircon ages of massive or foliated granitoids newly determined in this study range from
464 ca. 75 to 69 Ma (Figs. 8, 10). Taking into account the U–Pb zircon ages of gneissose granitoids
465 that are concordant with the main metamorphic foliation ([Takatsuka et al., 2018](#)), three magmatic
466 pulses with a different spatial distribution and timing are recognized in the Mikawa area (Fig. 10).
467 The oldest pulse occurred at ca. 99–95 Ma (Fig. 10); it is represented by gneissose granitoids
468 which are mainly enclosed inside younger plutons in the central part of the area (Kamihara tonalite,
469 Kiyosaki granodiorite). The subsequent pulse occurred at ca. 81–75 Ma (Fig. 10); it corresponds
470 to gneissose granitoids which concordantly intruded into metamorphic rocks in the southern
471 (deeper) part of the area (‘81–75 Ma Hbl–Bt tonalite’, ‘78–75 Ma (Hbl)–Bt granite’). The 99–95

472 Ma and 81–75 Ma magmatic rocks presently form elongated belts parallel to the NE–SW striking
473 regional foliation of metamorphic rocks (Fig. 10). The youngest pulse occurred at ca. 75–69 Ma;
474 massive to moderately-foliated granitoids intruded throughout the area and discordantly cut the
475 metamorphic fabrics and zones (Shinshiro tonalite, Mitsuhashi granodiorite, Inagawa granite and
476 Busetsu granite). For each pulse, the approximate surface exposure is $\sim 135 \text{ km}^2$, $\sim 110 \text{ km}^2$ and
477 $\sim 980 \text{ km}^2$ with decreasing age (Table S5).

478 The intrusion depth of the 99–95 Ma pulse plutons remains obscure because these oldest
479 intrusions are either surrounded by younger granitoids (Fig. 10) or in contact with metamorphic
480 rocks in which the contribution of contact and regional metamorphism is hard to evaluate (e.g.
481 [Miyake et al., 2016](#)). Our best observation comes from a km-scale band of metamorphic rocks
482 (Fig. 1) in between the gneissose Kamihara tonalite (99 Ma) and the massive Busetsu granite (70
483 Ma). There, pre-tectonic And (partly transformed to Sil) porphyroblasts overgrown by Crd (Fig.
484 3i, j) indicate low- P metamorphism in the andalusite stability field ($< 0.38 \text{ GPa}$) before the
485 intrusion of the post-tectonic Busetsu granite. If the grain size and chiastolite texture are regarded
486 as a result of reaction overstepping due to rapid temperature increase (e.g. [Waters and Lovegrove,](#)
487 [2002](#)), the porphyroblasts might be correlated with contact metamorphism at the margin of the
488 Kamihara pluton. This assumption is used to propose a relatively shallow intrusion depth (< 14
489 km; density of the crustal rocks is assumed to be 2.75 g/cm^3 throughout this paper) for the 99–95

490 Ma plutons.

491 For the 81–75 Ma pulse, the results of Al-in-hornblende geobarometry indicate that the
492 ‘81–75 Ma Hbl–Bt tonalite’ (sample GY81B) and the ‘78–75 Ma (Hbl)–Bt granite’ (sample
493 GY33A) intruded at a mid-crustal depth of ~19–24 km (Fig. 10). These data are consistent with
494 the crystallization depth deeper than 17.5 km proposed for tonalitic rocks in the Hazu area
495 (Masumoto et al., 2014), a part of the ‘81–75 Ma Hbl–Bt tonalite’ body (Fig. 10). The youngest
496 75–69 Ma pulse granitoids generate contact metamorphic aureoles which allow estimating their
497 emplacement levels (Fig. 10). Using pressure estimates from contact aureoles around the
498 Shinshiro tonalite and the Mitsuhashi granodiorite (0.23–0.24 GPa; Endo and Yamasaki, 2013)
499 and around the Inagawa granite (0.32 GPa; Miyake et al., 2016), the emplacement depth of these
500 granitoids is estimated at ~ 9–12 km. The Busetsu granite is contemporaneous with these
501 granitoids, intrudes all of them (Ryoke Research Group, 1972), and its southern margin overprints
502 the Bt zone for which a peak pressure is estimated at 0.34 GPa (Miyazaki, 2010), suggesting that
503 this granite intruded at a depth of ~ 13 km. Therefore, all data indicate that the 75–69 Ma pulse
504 granitoids were emplaced at a nearly similar depth of ~ 9–13 km.

505

506 **7.3. Plutono-metamorphic evolution of the Ryoke belt in the Mikawa area**

507 The plutono-metamorphic evolution of the Ryoke belt in the Mikawa area during the Cretaceous

508 flare-up starts with the intrusion of the 99–95 Ma pulse granitoids into the shallow levels of the
509 crust (< 14 km) and contemporaneous high-*T* regional metamorphism at the mid-crustal depth
510 (Fig. 11a). The similar NE–SW orientation of the gneissose structure in granitoids and the
511 foliation in metamorphic rocks suggests that the 99–95 Ma pulse granitoids probably acquired
512 their final structure during regional deformation after their intrusions (Fig. 11). The 99–95 Ma
513 pulse granitoids are not affected by a strong metamorphic overprint, which supports their original
514 intrusion into a relatively shallow level (< 14 km) of the former accretionary complex (Fig. 11a).
515 A direct evidence for contemporaneous high-*T* regional metamorphism and partial melting at
516 depth is given by the analysis of zircon rims in a leucosome sample from the Grt–Crd zone; the
517 inner rims of zircon containing sillimanite and the outer rims of zircon yield weighted average
518 U–Pb ages of 97.0 ± 4.4 Ma and 88.5 ± 2.5 Ma, respectively (sample GY03D; Figs. 6, 9a–d). An
519 indirect evidence is the presence of sillimanite-bearing, low Th/U metamorphic mantles in zircon
520 grains from the Busetsu granite (domain B; Fig. 5b–g). Considering that zircon in high-*T*
521 metamorphic rocks mostly grows in the presence of anatectic melt (e.g. [Roberts and Finger, 1997](#);
522 [Kawakami et al., 2013](#)), the metamorphic mantles (Fig. 5b–g) point to sillimanite-stable,
523 suprasolidus conditions in the source zone or intrusion pathway of the Busetsu granite at ca.
524 95–84 Ma.

525 The Grt–Crd zone was still at sillimanite-grade hypersolidus conditions at ca. 90 Ma as

526 indicated by the age of zircon rims in the pegmatite sample (GY47A; 90.1 ± 1.2 Ma). The dynamic
527 crystallization microtextures developed at grain boundaries of K-feldspar and quartz (Fig. 31)
528 suggests ductile deformation of the Grt–Crd zone rocks after the solidification of the pegmatite
529 at ca. 90 Ma. The youngest zircon age in domain B of zircon from the Busetsu granite (ca. 84 Ma)
530 can be taken as the onset of final cooling towards subsolidus conditions in the Sil–Kfs or Grt–Crd
531 zones. These observations imply that heat flow from the lower crust could no longer sustain
532 hypersolidus, regional high- T conditions at the end of this stage.

533 The second stage corresponds to another magmatic pulse from ca. 81 to 75 Ma (Fig.
534 11c). The 81–75 Ma pulse granitoids intruded in a relatively deep crustal level (> 18 km); Al-in-
535 hornblende geobarometry results for tonalitic rocks (0.50–0.64 GPa) are almost equivalent to
536 peak pressure estimates for the Grt–Crd zone (0.43–0.57 GPa; [Miyazaki, 2010](#)), indicating that
537 no significant exhumation had occurred before ca. 81 Ma. The 81–75 Ma gneissose granitoids
538 commonly preserve a magmatic foliation which is parallel to that of the host metamorphic rocks;
539 this points to a syn-tectonic emplacement at relatively high- T conditions, but based on age
540 differences, [Takatsuka et al. \(2018\)](#) interpreted that these granitoids were not the direct cause of
541 the high- T regional metamorphism. Some 81–75 Ma gneissose granitoids also exhibit solid-state
542 foliations ([Takatsuka et al., 2018](#)) indicating that they were deformed in a ductile manner even
543 after magma solidification. This observation is used to infer that syn-tectonic cooling and

544 exhumation of the Grt–Crd zone started just after the youngest deep intrusion, i.e., after ca. 75
545 Ma (Fig. 11d).

546 The final stage corresponds to the intrusion of the 75–69 Ma pulse granitoids (Fig. 11e).

547 For granitoids emplaced at that time, U–Pb zircon ages range from ca. 75 to 69 Ma while K–Ar

548 ages on biotite are only slightly younger and cluster at ca. 71–68 Ma (Table 1). Such a fast cooling

549 history implies that the host metamorphic rocks into which the 75–69 Ma pulse granitoids

550 intruded were relatively cold, possibly at a temperature below the closure temperature of the K–Ar

551 system in biotite (340–360 °C; [Hodges, 2005](#)). In addition, all the 75–69 Ma pulse granitoids

552 were emplaced at ~9–13 km depth (Figs. 10, 11e) and discordantly cut the regional metamorphic

553 zones (e.g., [Ryoke Research Group, 1972](#); Fig. 1). The cold and shallow environment inferred for

554 the intrusion of the 75–69 Ma pulse granitoids requires that the metamorphic section, especially

555 the Grt–Crd zone, had already been exhumed by ca. 70 Ma; it is best explained by a northward

556 tilting of both the metamorphic rocks and gneissose granitoids (Fig. 11d). The average

557 exhumation rate of the Grt–Crd zone metamorphic rocks between ca. 75 and 70 Ma is estimated

558 at 0.80–2.4 km/Myr (0.80–2.4 mm/yr), which is slightly faster than the present-day erosion speed

559 across the Japanese Islands excepting high-elevation areas (<0.75 mm/yr; [Fujiwara et al., 1999](#)).

560

561 **8. Insights into the tectono-thermal response of the crust during a flare-up event**

562 **8.1. Succession of granitoid emplacement depths**

563 One of the important features of the flare-up history revealed in this study is the sequence of
564 granitoid emplacement depths. Pre-tectonic chiastolite found around the Kamihara tonalite (Fig.
565 3i–j) is used to propose a shallow intrusion level for the 99–95 Ma pulse granitoids. If this is
566 accepted, the plutono-metamorphic evolutions in the western (Yanai area; [Skrzypek et al., 2016](#))
567 and the eastern (Mikawa area; this study) parts of the Ryoke belt reveal a common feature. In the
568 Mikawa area, plutonic activity started with shallow intrusions (< 14 km), and was followed by
569 deeper (18–24 km) and finally shallow ones (9–13 km; Figs. 11, 12). A similar cycle is recognized
570 in the Yanai area where the oldest and shallow intrusions (< 14 km at ca. 105–100 Ma) are
571 followed by deeper (~ 22 km at ca. 100 Ma) and again shallow (< 14 km at ca. 95 Ma) plutons
572 ([Skrzypek et al., 2016](#); Fig. 12).

573 The final emplacement level of magmatic intrusions in upper crustal regions is thought
574 to depend on the interaction of rheology and rigidity contrasts within the crust, the crustal stress
575 field, and the crustal and lithospheric density structure ([Burov et al., 2003](#); [Schubert et al., 2013](#)).
576 It can also be controlled by the preexisting geological structures that facilitate or prevent its ascent
577 ([Brown, 2013](#); [Petri et al., 2017](#); [Vigneresse and Clemens, 2000](#)). Importance of the tectonic
578 control on the intrusions of granitoids during the flare-up is inferred from the syn-tectonic nature
579 of the 81–75 Ma pulse granitoids. However, the shallow granitoids of the first pulses are

580 considered pre-tectonic both in the Yanai and Mikawa areas. The temporal coincidence between
581 the hypersolidus stage of regional metamorphism and the 99-95 Ma pulse in the Mikawa area
582 (Fig. 12) suggests that the prograde stage of regional metamorphism should have already started
583 before the intrusion of the 99–95 Ma pulse. In addition, the intrusion of the deep 81–75 Ma pulse
584 granitoids occurred after the highest-grade regional metamorphic zone (Grt–Crd zone) cooled
585 below the solidus temperature at 88.5 ± 2.5 Ma. These coincidences between granite emplacement
586 depths and changes in the thermal structure suggest that emplacement levels of the plutons may,
587 to some extent, be controlled by the thermal structure of the crust at their intrusion timings. The
588 yield strength of the crust may have been lowered through heating, and this may have enabled
589 granitoid magmas to be emplaced in relatively shallow crustal levels (e.g., [Schubert et al., 2013](#)).
590 In the case of diapiric ascent of magmatic bodies, however, numerical models suggest that the
591 effect of background thermal structure on the emplacement depth of plutons are in the order of
592 several km ([Burov et al., 2003](#)). Therefore, the change in emplacement level of plutons (~ 10 km
593 depth difference) should also be controlled by other factors such as tectonics during the granitoid
594 intrusion. Whether similar link between high background thermal structure and granitoid
595 emplacement in shallow levels of the crust exists for the 75-69 Ma pulse or not is unknown,
596 because the metamorphic zones were already inclined at the timing of the 75-69 Ma pulse
597 intrusion and thus the middle crust of that time is presently not exposed (Fig. 11e). The vertical

598 movement of the granitoid magmas of the 75-69 Ma pulse could have potentially been facilitated
599 by existing geologic structures in the crust, such as inclined foliation planes (e.g., [Brown, 2013](#)),
600 since the foliation planes of the host metamorphic rocks had already been tilted by this stage (Fig.
601 11d–e).

602

603 **8.2. Transient thermal anomaly in the mantle and formation of low-*P/T* type regional** 604 **metamorphic zones**

605 In the Mikawa area, the absence of syn-metamorphic (ca. 97–89 Ma) granitoids in the highest-
606 grade Grt–Crd zone and the relatively long duration of regional hypersolidus conditions ($> 8.5 \pm$
607 5.1 Myr) point to prolonged heating of the middle crust. The upper-middle continental crust is
608 made up of an accretionary complex in which the amount of radiogenic heat producing elements
609 is equivalent to the average continental crust values (Togashi et al., 2000). Even relatively deep
610 granitoid intrusions hardly generate hypersolidus conditions longer than ca. 1 Ma (e.g. [Okudaira](#)
611 [et al., 1996](#)), so that thermal conduction from the lower crust, heated up by the transient thermal
612 input from the mantle, can only satisfactorily explain such a prolonged low-*P/T* type regional
613 metamorphism. Numerical modelling shows that transient thermal anomalies in the mantle can
614 significantly raise the temperature of mid-crustal rocks (Bodorkos et al., 2002) and points to the
615 importance of thermal conduction. We do not deny the importance of thermal input by advection
616 of granitoids, but emphasize the relative importance of thermal conduction from the lower crust

617 compared to the supplementary thermal input by advection of magmatic bodies in the case of the
618 prolonged low- P/T type regional metamorphism.

619 Our dataset suggest that start of the Cretaceous flare-up event was controlled by the
620 increase in thermal input from the mantle. Numerical models suggest that about 10 Myr is required
621 for the middle crust to reach the highest- T condition after 5 Myr of duration of 1300 °C in the mantle
622 lithosphere nearly at the bottom of the crust (Bodorkos et al., 2002). Accordingly, the mantle anomaly
623 must have predated the first granitoid pulse. Whether the pattern of granitoid pulses directly reflects
624 a succession of thermal pulses in the mantle or a pulsatile crustal response to a single mantle anomaly
625 (de Silva et al., 2015) remains an important problem to be solved.

626 Estimating the amount of magma addition to the arc crust is a delicate issue. In the
627 Mikawa area, the 75–69 Ma granitoids are contemporaneous with the Nohi rhyolite, a voluminous
628 volcanic complex consisting of caldera-related felsic rocks (ignimbrites, lavas, volcanoclastic
629 rocks, intrusives etc.) erupted at ca. 70 Ma (U–Pb zircon dating, Hoshi et al., 2016). However,
630 the relative importance of the 75–69 Ma pulse with respect to the older ones is not necessarily
631 higher (Fig. 12). Erosion can be responsible for the loss of a volcanic sequences corresponding to
632 the 99–95 Ma pulse, and the fact that the presently exposed crustal level is subparallel to the
633 intrusion level of the 75–69 Ma pulse plutons might overemphasize the volume of magma added
634 during the last pulse (Figs. 10, 11e). Taken together the magmatic pulses occurring from ca. 99

635 Ma to ca.69 Ma in the eastern part of the Ryoke belt may reflect transient thermal inputs from the
636 mantle and resulting partial melting of the lower crust to produce the granitoids, and point to a
637 significant addition of continental material into the metasedimentary upper-middle crust of the
638 Eurasian continental margin during the Cretaceous flare-up event.

639

640 **9. Conclusions**

641 The Cretaceous flare-up event which can be deciphered in the eastern part of the Ryoke belt (SW
642 Japan) reveals the following features and implications for crustal evolution:

643 (1) Three plutonic pulses occurred at ca. 99–95, ca. 81–75 and ca. 75–69 Ma, with the first
644 granitoid pulse being contemporaneous with the hypersolidus stage of the low-*P/T* type
645 regional metamorphism (97.0 ± 4.4 Ma to 88.5 ± 2.5 Ma).

646 (2) In spite of the temporal association, the absence of spatial association between the highest-
647 grade regional metamorphic zone and pre- to syn-metamorphic granitoids supports the
648 presence of a transient thermal anomaly in the mantle and thermal conduction as the main
649 process responsible for the formation of the low-*P/T* type regional metamorphic zones.

650 (3) The plutons were successively emplaced in a shallow (< 14 km), deeper (~18–24 km) and
651 shallow (~9–13 km) levels of the crust, with emplacement depths probably controlled by the
652 combination of thermal structural change of the crust and tectonics during granitoid intrusions.

653 (4) Estimates of the respective volume of magma added during each pulse are biased by the
654 present-day exposures; yet the 75–69 Ma pulse event clearly documents a voluminous
655 addition of granitic material to the arc crust through both plutonic and volcanic activities.

656

657 **Acknowledgements**

658 We are grateful to T. Okudaira and S. Endo for reviews and M. Scamberulli for editorial efforts.
659 K. Tani, T. Nakajima and K. Suzuki are thanked for discussions on the granitoids of the Ryoke
660 belt. Thanks are also due to K. Horie, M. Takehara, T. Kogiso and Y. Monta for assisting sample
661 preparation and to F. Higashino for assistance in U–Pb zircon dating. This study was financially
662 supported by JSPS KAKENHI Grant No. 26400513 and NIPR general collaboration project No.
663 28-25 to Kawakami, and by a JSPS postdoctoral fellowship to Skrzypek (Grant No. 25-03715 to
664 T. Hirajima).

940 Fig. 1. (a) Simplified geological map showing the location of the Ryoke belt across Japan. (b)

941 Geological map of the Ryoke belt in central Japan with metamorphic zones. Sample localities
942 of granitoids and a metamorphic rock (GY92A) are indicated. The geological map is
943 compiled and modified after Makimoto et al. (2004), Miyazaki et al. (2008), Nakashima et
944 al. (2008), Miyazaki (2010), Yamasaki and Ozaki (2012), Endo and Yamasaki (2013), the
945 Geological Survey of Japan (2015), Miyake et al. (2016) and Takatsuka et al. (2018). MTL;
946 Median Tectonic Line. ISTL; Itoigawa-Shizuoka Tectonic Line. Mineral abbreviations are
947 after Kretz (1983).

948 Fig. 2. Field occurrence and slab photographs of granitoid samples used for U–Pb zircon dating.

949 (a) Outcrop of the Shinshiro tonalite (GY50A) showing ellipsoidal mafic enclaves (dark
950 color) elongated parallel to the gneissose structure. Surface is partly green because of moss.

951 (b) Slab photograph of the Shinshiro tonalite (sample GY100A) showing a gneissose
952 structure defined by the arrangement of Hbl + Bt. (c) Slab photograph of the Mitsuhashi

953 granodiorite (sample GY99A) showing a gneissose structure defined by the arrangement of
954 Hbl + Bt. (d, e) Slab photographs of the Inagawa granite: sample GY86A from the gneissose

955 porphyritic facies and sample GY93A from the massive facies. (f, g) Field occurrence of the
956 Busetsu granite: (f) Xenolith of pelitic schist in garnet-bearing, fine-grained granite. (g)

957 Intrusion boundary of fine-grained granite and meta-sandstone. Foliation of the meta-
958 sandstone is oblique to the boundary. (h) Slab photograph of the Busetsu granite (sample

959 GY89A) showing a gneissose structure and K-feldspar megacrysts. (i) Field occurrence of
960 ~20 cm thick leucosome (GY03D) subparallel to the migmatitic banding of the psammitic
961 metatexite. (j) Field occurrence of pegmatite sample GY47A (white). Mafic lens is present
962 above the pegmatite.

963 Fig. 3. Photomicrographs of granitoid and pelitic gneiss samples. (a, b) Samples GY50A and
964 GY100A from the Shinshiro tonalite showing the mode of occurrence of zircon and allanite
965 (plane polarized light, PPL). (c) Sample GY99A from the Mitsuhashi granodiorite showing
966 the mode of occurrence of zircon (PPL). (d, e) Samples GY86A and GY93A from the
967 Inagawa granite showing the mode of occurrence of zircon and allanite (PPL) (f, g) Samples
968 GY51A and MK02M from the Busetu granite (PPL) showing the mode of occurrence of
969 zircon. These samples are characterized by the presence of garnet and muscovite. (h) Sample
970 GY89A from the Busetu granite (crossed polarized light, CPL) showing a gneissose
971 structure defined by the arrangement of Bt + Ms, and dynamic recrystallization of quartz in
972 elongated layers. (i) Pelitic gneiss (sample GY92A1) from a km-wide band of
973 metasedimentary rocks in between the Kamihara and Busetu plutons. Andalusite with a
974 chiastolite texture (partly transformed to sillimanite) is replaced by pinitized cordierite at the
975 rim. The main foliation defined by the arrangement of biotite and fibrolite is deflected around
976 the andalusite porphyroblast. See text for details. PPL. (j) CPL of (i). (k) Thin section photo

977 of leucosome sample GY03D. CPL. (l) Thin section photo of pegmatite sample GY47A.
978 Fine-grained myrmekite is abundant along grain boundaries of K-feldspar, where sillimanite
979 and secondary muscovite is also common. CPL.

980 Fig. 4. Cathodoluminescence images of representative zircon grains showing analyzed spots and
981 results of U–Pb dating. Concordant and discordant data are shown in yellow and white
982 characters, respectively. Results are labeled with spot number, $^{206}\text{Pb}/^{238}\text{U}$ age $\pm 2\sigma$ error (Ma),
983 and concordance in parenthesis (%). Scale bars represent 20 μm . (a–f) Shinshiro tonalite
984 samples (GY50A and GY100A), (g, h) Mitsuhashi granodiorite sample (GY99A), (i–l)
985 Inagawa granite samples (GY86A and GY93A).

986 Fig. 5. Cathodoluminescence and BSE images of representative zircon grains from the Busetsu
987 granite (samples GY51A, MK02M and GY89A) with analyzed spots and results of U–Pb
988 dating. Concordant and discordant data are shown in yellow and white characters,
989 respectively. Results are labeled with spot number, $^{206}\text{Pb}/^{238}\text{U}$ age $\pm 2\sigma$ error (Ma), Th/U ratio,
990 and concordance in parenthesis (%). Alphabets representing the domain name (B, C or D)
991 are also added to (b–i). Scale bars represent 20 μm . (a) Zircon with domain A alone (b–d)
992 Zircons with inherited core, domain B and domain D. Red arrows indicate sillimanite
993 inclusions. (e–g) Zircons with domains B and C. (h, i) Zircons with domains C and D. (j–m)
994 Zircons with domain D alone. See text for detailed explanation of the domains. A histogram

995 and relative probability diagram for $^{206}\text{Pb}/^{238}\text{U}$ ages obtained with all Busetsu granite samples
996 (GY51A, MK02M and GY89A, concordant data only) is also shown.

997 Fig. 6. Cathodoluminescence and BSE images of representative zircon grains from a migmatite
998 leucosome sample GY03D. Scale bars represent 20 μm .

999 Fig. 7. Cathodoluminescence and BSE images of representative zircon grains from a pegmatite
1000 sample GY47A. Scale bars represent 20 μm .

1001 Fig. 8. Concordia diagrams for U–Pb zircon dating results for (a, b) Shinshiro tonalite (samples
1002 GY50A and GY100A), (c) Mitsuhashi granodiorite (sample GY99A), (d, e) Inagawa granite
1003 (samples GY86A and GY93A), and (f–h) Busetsu granite (samples GY51A, MK02M and
1004 GY89A). Concordant and discordant data are plotted together for each sample. Rejected data
1005 (See Table S2 and text for details) are not shown.

1006 Fig. 9. Relative probability diagrams, concordia diagrams and U-concentration vs age plot for
1007 U–Pb zircon dating of migmatites and a pegmatite. (a) Relative probability diagram for
1008 sample GY03D. (b) Concordia diagram for sample GY03D. (c) U-concentration (ppm) vs
1009 $^{206}\text{Pb}/^{238}\text{U}$ age $\pm 2\sigma$ error (Ma) plot for sample GY03D. (d) Th/U ratio vs $^{206}\text{Pb}/^{238}\text{U}$ age $\pm 2\sigma$
1010 error (Ma) plot for sample GY03D. (e) Concordia diagram for sample GY47A. (f) Relative
1011 probability diagram for sample GY47A.

1012 Fig. 10. Summary of U–Pb zircon ages and spatial distribution of plutonic rocks in the Mikawa

1013 area (This study; Takatsuka et al., 2018; Tani et al., 2014; Nakajima et al., 2004; Murakami
1014 et al., 2006). U–Pb zircon ages are shown as $^{206}\text{Pb}/^{238}\text{U}$ ages with 2σ uncertainties. Also
1015 shown are pressure estimates of granitoid crystallization by Al-in-hornblende barometry
1016 (This study; Masumoto et al., 2014) and P – T estimates for contact metamorphism around
1017 the 75–69 Ma granitoids (Shinshiro tonalite, Mitsuhashi granodiorite, Inagawa granite and
1018 Busetsu granite) (This study; Adachi and Wallis, 2007; Endo and Yamasaki, 2013; Miyake
1019 et al., 1992; 2016).

1020 Fig. 11. Schematic drawings summarizing the plutono-metamorphic evolution of the Ryoke belt
1021 in the Mikawa area. Note that different colors of zircon illustrations in different phases of
1022 granitoids finally appears altogether in the Busetsu granite. (a) ca. 99–95Ma: Emplacement
1023 of granitoids in a shallow part of the accretionary complex. Zircon in the 99–95 Ma
1024 granitoids is shown in blue. (b) ca. 95–85 Ma: High- T regional metamorphism and partial
1025 melting at depth. Leucosomes and metamorphic zircon (shown in gray) form in the
1026 migmatitic Grt–Crd zone. (c) ca. 81 Ma: Emplacement of the gneissose granitoids in the
1027 middle crust. Zircon in 81–75 Ma granitoids is shown in orange. (d) ca. 75 Ma: Late-
1028 magmatic (and probably syn-tectonic) exhumation of the high-grade metamorphic zones; the
1029 regional metamorphic zonation is tilted toward the north. (e) ca. 75–69 Ma: emplacement of
1030 the 75–69 Ma granitoids at shallow crustal level. Inset shows the complex zircon record in

1031 the Busetsu granite. Zircon crystal shown by pink is a direct crystallization product from the
1032 Busetsu granite, and zircons sourced from other plutons and metamorphic rocks has pink
1033 rims representing the overgrowth during the crystallization of the Busetsu granite.

1034 Fig. 12. Relative probability diagram of surface exposure of granitoids plotted against U–Pb
1035 zircon ages for the Mikawa and Yanai areas (this study; Skrzypek et al., 2016; in press;
1036 Takatsuka et al., 2018). Note the scale difference between two areas. Time periods shaded in
1037 gray (*HT*) represent the duration of high-*T* metamorphism in each area, estimated based on
1038 the age range of metamorphic zircons (this study; Skrzypek et al., 2016). Although not shown
1039 in the figure, the central part of the Hiroshima Granite around Hiroshima and Kabe regions
1040 (~40 km east of the Yanai area) are reported to give zircon U-Pb ages of 87.3 ± 0.9 to $85.6 \pm$
1041 1.0 Ma (Tani et al., 2014). See Table S5 for data and a detailed method used to construct this
1042 figure.

1043 Table 1. Summary of published geochronological data for granitoids in the Mikawa area.

1044 Table 2. Summary of U–Pb zircon dating results for granitoids, migmatite and pegmatite in the
1045 Mikawa area obtained in this study.

Laser ablation system	NWR193 Excimer ArF (ESI, Portland, USA) Two volume cell 193 nm Laser wave length 5 ns Pulse duration 2.8–5.4 J/cm ² Fluence 4.5 Hz Repetition rate 10 µm Ablation pit size Single hole drilling Sampling mode Pre-cleaning 1 shot with 15 µm Carrier gas He gas and Ar make-up gas combined outside ablation cell He gas flow rate 0.60 l/min Ar make-up gas flow rate 0.86 l/min Ablation duration 20, 25 seconds Signal smoothing device Baffle type (Tunheng and Hirata, 2004)	Laser ablation system	NWR193 Excimer ArF (ESI, Portland, USA) Two volume cell 193 nm Laser wave length 5 ns Pulse duration 5.3–5.5 J/cm ² Fluence 3 Hz Repetition rate 20 µm Ablation pit size Single hole drilling Sampling mode Pre-cleaning 1 shot with 25 µm Carrier gas He gas and Ar make-up gas combined outside ablation cell He gas flow rate 0.60 l/min Ar make-up gas flow rate 0.86 l/min Ablation duration 33 seconds Signal smoothing device Baffle type (Tunheng and Hirata, 2004)	Laser ablation system	NWR213 Nd:YAG laser (ESI, Portland, U.S.A.) Two volume cell 213 nm Laser wave length <5 ns Pulse duration 3.5–4.5 J/cm ² Fluence 5 Hz Repetition rate 10 or 20 µm Ablation pit size Single hole drilling Sampling mode Pre-cleaning 1 shot with 15 or 35 µm Carrier gas He gas and Ar make-up gas combined outside ablation cell He gas flow rate 0.60–0.85 l/min Ar make-up gas flow rate 1.4–1.5 l/min Ablation duration 10 s Signal smoothing device Baffle type (volume: 120 ml)
ICP Mass Spectrometer	Nu Plasma II HR-MC-ICP-MS (Nu Instruments, Wrexham, U.K.) Instrument 1300 W RF power Integration of total ion counts per single ablation. Signals obtained from first few seconds were not used for data reduction, and next signals obtained from 10 seconds were integrated for further calculations. Signal intensity of ²³⁸ U was not monitored and ²⁰⁶ Pb/ ²³⁸ U is calculated assuming ²³⁸ U/ ²³⁵ U = 137.88 (Jaffey et al., 1971).	ICP Mass Spectrometer	Nu Plasma II HR-MC-ICP-MS (Nu Instruments, Wrexham, U.K.) Instrument 1300 W RF power Integration of total ion counts per single ablation. Signals obtained from first few seconds were not used for data reduction, and next signals obtained from 22 seconds were integrated for further calculations. Signal intensity of ²³⁸ U was not monitored and ²⁰⁶ Pb/ ²³⁸ U is calculated assuming ²³⁸ U/ ²³⁵ U = 137.88 (Jaffey et al., 1971).	ICP Mass Spectrometer	Agilent 8800 (Agilent Technology, Santa Clara, California, U.S.A.) Instrument 1310 W RF power Integration of total ion counts per single ablation. Signals obtained from first few seconds were not used for data reduction, and next signals obtained from 15 s were integrated for further calculations. Signal intensity of ²³⁸ U was not monitored and ²⁰⁶ Pb/ ²³⁸ U is calculated assuming ²³⁸ U/ ²³⁵ U = 137.88 (Jaffey et al., 1971). Oxide ions of Th and U (ThO ⁺ and UO ⁺) were monitored and used for further calculation instead of Th ⁺ and U ⁺ .
Data reduction	Multiple collector mode using six ion counters (IC and D) and a faraday collector (H)	Data reduction	Multiple collector mode using six ion counters (IC and D) and a faraday collector (H)	Data reduction	Pulse counting mode by an ion counter
Detection mode	(H)	Detection mode	(H)	Detection mode	MS/MS mode Collision/reaction gas and flow rate NH ₃ (1.9 ml/min) and He (9 ml/min) for reduction of isobaric interference from mercuriv (Kasaoo8u et al., 2016)
Monitored isotopes	²⁰² Hg, ²⁰⁴ Hg + Pb, ²⁰⁶ Pb, ²⁰⁷ Pb, ²⁰⁸ Pb, ²³² Th, ²³⁵ U	Monitored isotopes	²⁰² Hg, ²⁰⁴ Hg + Pb, ²⁰⁶ Pb, ²⁰⁷ Pb, ²⁰⁸ Pb, ²³² Th, ²³⁵ U	Monitored mass peak (amu) and permeable mass value for first quadrupole (Q1) and second quadrupole (Q2)	202 (Hg: Q1 = 202; Q2 = 202), 204 (Hg + Pb; Q1 = 204; Q2 = 204), 206 (Pb; Q1 = 206; Q2 = 206), 207 (Pb; Q1 = 207; Q2 = 207), 248 (ThO; Q1 = 248; Q2 = 248), 254 (UO; Q1 = 254; Q2 = 254)
Detector	IC4 for ²⁰² Hg, IC3 for ²⁰⁴ (Hg + Pb), D2 for ²⁰⁶ Pb, D1 or IC1 for ²⁰⁷ Pb, IC0 for ²⁰⁸ Pb, ICS for ²³² Th, and H9 for ²³⁵ Th	Detector	IC4 for ²⁰² Hg, IC3 for ²⁰⁴ (Hg + Pb), D2 for ²⁰⁶ Pb, IC1 for ²⁰⁷ Pb, IC0 for ²⁰⁸ Pb, ICS for ²³² Th, and H9 for ²³⁵ Th	Integration time per mass peak	202 (5 ms), 204 (10 ms), 206 (50 ms), 207 (50 ms), 248 (20 ms), 254 (50 ms)
Integration time per peak	10 seconds for ²⁰² Hg, ²⁰⁴ (Hg + Pb), ²⁰⁶ Pb, ²⁰⁷ Pb, ²⁰⁸ Pb, ²³² Th, ²³⁵ U	Integration time per peak	22 seconds for ²⁰² Hg, ²⁰⁴ (Hg + Pb), ²⁰⁶ Pb, ²⁰⁷ Pb, ²⁰⁸ Pb, ²³² Th, ²³⁵ U	Total integration time per reading	0.2047 s
Total integration time per reading	0.4 seconds	Total integration time per reading	0.4 seconds	Integration time per single ablation	15 s
Formation rate of Th oxide (²³²Th³²O⁺/²³²Th⁺)	<0.3%	Formation rate of Th oxide (²³²Th³²O⁺/²³²Th⁺)	<0.3%	Integration time per single ablation	46.8
Data processing	Gas blank counts (20 seconds) acquired before each single measurement and linearly subtracted with a step forward method 91500 zircon was used in correction for Pb/U and Th/U fractionation in all measurements. NIST SRM610 was used for correction of Pb/Pb fractionation. All correction factor for elemental and isotopic fractionation are determined by linear interpolation. GI-1 (600.39 ± 0.65 Ma, Jackson et al., 2004) and Plešovice (337.13 ± 0.37 Ma, Sláma et al., 2008) and OD-3 (32.853 ± 0.016 Ma, Lukács et al., 2015) were used as secondary reference material for validation of accuracy ²⁰⁶ Pb/ ²³⁸ U = 0.1792, ²⁰⁶ Pb/ ²³² Th = 0.05374, U concentration = 81.2 µg/g, Th concentration = 28.6 µg/g, Pb concentration = 14.8 µg/g (91500, Wiedenbeck et al., 1995), ²⁰⁷ Pb/ ²³⁵ Pb = 0.9096, ²⁰⁶ Pb/ ²³⁸ Pb = 17.045, ²⁰⁷ Pb/ ²⁰⁶ Pb = 15.504, ²⁰⁶ Pb/ ²⁰⁸ Pb = 36.964 (NIST SRM 610, Jochum and Brueckner, 2008).	Data processing	Gas blank counts (20 seconds) acquired before each single measurement and linearly subtracted with a step forward method 91500 zircon was used in correction for Pb/U and Th/U fractionation in all measurements. NIST SRM610 was used for correction of Pb/Pb fractionation. All correction factor for elemental and isotopic fractionation are determined by linear interpolation. GI-1 (600.39 ± 0.65 Ma, Jackson et al., 2004) and Plešovice (337.13 ± 0.37 Ma, Sláma et al., 2008) were used as secondary reference material for validation of accuracy ²⁰⁶ Pb/ ²³⁸ U = 0.1792, ²⁰⁶ Pb/ ²³² Th = 0.05374, U concentration = 81.2 µg/g, Th concentration = 28.6 µg/g, Pb concentration = 14.8 µg/g (91500, Wiedenbeck et al., 1995), ²⁰⁷ Pb/ ²³⁵ Pb = 0.9096, ²⁰⁶ Pb/ ²³⁸ Pb = 17.045, ²⁰⁷ Pb/ ²⁰⁶ Pb = 15.504, ²⁰⁶ Pb/ ²⁰⁸ Pb = 36.964 (NIST SRM 610, Jochum and Brueckner, 2008).	Data processing	Gas blank counts were obtained for 15 s before each ablation pit and linearly subtracted with a step forward method. 91500 zircon was used in correction for Pb/U and Th/U fractionation in all measurements. NIST SRM610 was used for correction of Pb/Pb fractionation. All correction factor for elemental and isotopic fractionation are determined by linear interpolation. GI-1 (600.39 ± 0.65 Ma, Jackson et al., 2004) and Plešovice (337.13 ± 0.37 Ma, Sláma et al., 2008) were used as secondary reference material for validation of accuracy ²⁰⁶ Pb/ ²³⁸ U = 0.1792, U concentration = 81.2 µg/g, Th concentration = 28.6 µg/g, Pb concentration = 14.8 µg/g (91500, Wiedenbeck et al., 1995), ²⁰⁷ Pb/ ²³⁵ Pb = 0.9096, ²⁰⁶ Pb/ ²³⁸ Pb = 17.045, and ²⁰⁷ Pb/ ²⁰⁶ Pb = 15.504 for NIST SRM610 (Jochum and Brueckner, 2008).
Calibration strategy	GI-1 (600.39 ± 0.65 Ma, Jackson et al., 2004) and Plešovice (337.13 ± 0.37 Ma, Sláma et al., 2008) and OD-3 (32.853 ± 0.016 Ma, Lukács et al., 2015) were used as secondary reference material for validation of accuracy	Calibration strategy	GI-1 (600.39 ± 0.65 Ma, Jackson et al., 2004) and Plešovice (337.13 ± 0.37 Ma, Sláma et al., 2008) were used as secondary reference material for validation of accuracy	Calibration strategy	GI-1 (600.39 ± 0.65 Ma, Jackson et al., 2004) and Plešovice (337.13 ± 0.37 Ma, Sláma et al., 2008) were used as secondary reference material for validation of accuracy
Normalization values	²⁰⁶ Pb/ ²³⁸ U = 0.1792, ²⁰⁶ Pb/ ²³² Th = 0.05374, U concentration = 81.2 µg/g, Th concentration = 28.6 µg/g, Pb concentration = 14.8 µg/g (91500, Wiedenbeck et al., 1995), ²⁰⁷ Pb/ ²³⁵ Pb = 0.9096, ²⁰⁶ Pb/ ²³⁸ Pb = 17.045, ²⁰⁷ Pb/ ²⁰⁶ Pb = 15.504, ²⁰⁶ Pb/ ²⁰⁸ Pb = 36.964 (NIST SRM 610, Jochum and Brueckner, 2008).	Normalization values	²⁰⁶ Pb/ ²³⁸ U = 0.1792, ²⁰⁶ Pb/ ²³² Th = 0.05374, U concentration = 81.2 µg/g, Th concentration = 28.6 µg/g, Pb concentration = 14.8 µg/g (91500, Wiedenbeck et al., 1995), ²⁰⁷ Pb/ ²³⁵ Pb = 0.9096, ²⁰⁶ Pb/ ²³⁸ Pb = 17.045, ²⁰⁷ Pb/ ²⁰⁶ Pb = 15.504, ²⁰⁶ Pb/ ²⁰⁸ Pb = 36.964 (NIST SRM 610, Jochum and Brueckner, 2008).	Normalization values	²⁰⁶ Pb/ ²³⁸ U = 0.1792, U concentration = 81.2 µg/g, Th concentration = 28.6 µg/g, Pb concentration = 14.8 µg/g (91500, Wiedenbeck et al., 1995), ²⁰⁷ Pb/ ²³⁵ Pb = 0.9096, ²⁰⁶ Pb/ ²³⁸ Pb = 17.045, and ²⁰⁷ Pb/ ²⁰⁶ Pb = 15.504 for NIST SRM610 (Jochum and Brueckner, 2008).
Common-Pb correction	Not made	Common-Pb correction	Not made	Common-Pb correction	Not made
Uncertainties	Uncertainties for ages and isotope ratios are quoted at 2 SD absolute, propagation is by quadratic addition. Reproducibility of primary reference material, counting statistics of measured isotope and background signal intensity are propagated (Sakata et al., 2014). GI-1 : Weighted ave. ²⁰⁶ Pb/ ²³⁸ U age = 603.8 ± 5.4 Ma (2 SD, MSWD = 1.03, n = 17, in 17 sessions), ²⁰⁷ Pb/ ²³⁵ U age = 603.1 ± 4.9 Ma (2 SD, MSWD = 0.68, n = 17, in 17 sessions) Plešovice : Weighted ave. ²⁰⁶ Pb/ ²³⁸ U age = 341.7 ± 4.1 Ma (2 SD, MSWD = 0.86, n = 7, in 7 sessions), ²⁰⁷ Pb/ ²³⁵ U age = 342.4 ± 4.4 Ma (2 SD, MSWD = 0.80, n = 7, in 7 sessions)	Uncertainties	Uncertainties for ages and isotope ratios are quoted at 2 SD absolute, propagation is by quadratic addition. Reproducibility of primary reference material, counting statistics of measured isotope and background signal intensity are propagated (Sakata et al., 2014). GI-1 : Weighted ave. ²⁰⁶ Pb/ ²³⁸ U age = 598.6 ± 8.5 Ma (2 SD, MSWD = 2.5, n = 9, in 9 sessions), ²⁰⁷ Pb/ ²³⁵ U age = 599.8 ± 5.5 Ma (2 SD, MSWD = 1.11, n = 9, in 9 sessions) Plešovice : Weighted ave. ²⁰⁶ Pb/ ²³⁸ U age = 342.3 ± 2.7 Ma (2 SD, MSWD = 0.87, n = 9, in 9 sessions), ²⁰⁷ Pb/ ²³⁵ U age = 341.0 ± 3.5 Ma (2 SD, MSWD = 0.37, n = 9, in 9 sessions)	Uncertainties	Uncertainties for ages and isotope ratios are quoted at 2 SD absolute, propagation is by quadratic addition. Reproducibility of primary reference material, counting statistics of measured isotope and background signal intensity are propagated (Sakata et al., 2014). GI-1 : Weighted ave. ²⁰⁶ Pb/ ²³⁸ U age = 602.1 ± 5.8 Ma (2 SD, MSWD = 0.71, n = 9, in 9 sessions), ²⁰⁷ Pb/ ²³⁵ U age = 605.7 ± 5.9 Ma (2 SD, MSWD = 0.28, n = 9, in 9 sessions) Plešovice : Weighted ave. ²⁰⁶ Pb/ ²³⁸ U age = 338.1 ± 3.3 Ma (2 SD, MSWD = 0.50, n = 9, in 9 sessions), ²⁰⁷ Pb/ ²³⁵ U age = 337.9 ± 3.6 Ma (2 SD, MSWD = 0.40, n = 9, in 9 sessions)
Quality control/validation	OD-3 : Weighted ave. ²⁰⁶ Pb/ ²³⁸ U age = 32.2 ± 0.5 Ma (2 SD, MSWD = 0.69, n = 10, in 10 sessions), ²⁰⁷ Pb/ ²³⁵ U age = 33.8 ± 1.1 Ma (2 SD, MSWD = 1.7, n = 10, in 10 sessions)	Quality control/validation		Quality control/validation

Surface exposure of each pulse is calculated as a total of surface exposure of each granitoid belonging to each pulses. The pulse names of each granitoids are listed in the 'Pulse' column.

Figure 12 was prepared with data presented in the table above.

Areas: Mikawa area (eastern part of the Ryoke belt); Yanai area (western part of the Ryoke belt)

Pluton: Pluton name following correlations in Skrzypek et al. (2016) and Takatsuka et al. (2018)

Age / Error (Ma): All available U – Pb zircon ages for the plutons considered. References can be found in Skrzypek et al. (2016), Takatsuka et al. (2018) and the present study.

Exposed area (m²): Exposed pluton area is calculated using the seamless geological map of Japan, scale 1: 200,000 (July 3, 2012 version) and for map extents corresponding to those of Fig.1 in Skrzypek et al. (2016) and Fig. 1 in the present study.

Calculation method: For each pluton, all available U – Pb zircon data are used to calculate an age probability density curve assuming a Gaussian distribution for each Age/Error pair. Each curve is then scaled so that its area corresponds to the exposed pluton area. The thick black curve represents the sum of all probability density curves for the individual plutons.

Limitations: Defining the age of a pluton based on a single sample cannot account for age heterogeneity. The assumption that a whole pluton preserves a single age within a 2 – 3 Ma error seems to be mostly valid, except when several facies are identified (Inagawa granite in the Mikawa area, Gamano granodiorite in the Yanai area). The estimated exposed pluton area is restricted to arbitrary map extents; the actual proportions may slightly vary.
