11 **Abstract**

12 This paper presents improvement and performance evaluation of the “perturbation
13 source method”, which is one of the Monte Carlo perturbation techniques. The formerly
14 proposed perturbation source method **was** first-order accurate, although it is known that
15 the method can be easily extended to an exact perturbation method. A transport equation
16 for calculating an exact flux difference caused by a perturbation is solved. A
17 perturbation particle representing a flux difference is explicitly transported in the
18 perturbed system, instead of in the unperturbed system. The source term of the transport
19 equation is defined by the unperturbed flux and the cross section (or optical parameter)
20 changes. The unperturbed flux is provided by an “on-the-fly” technique during the
21 course of the ordinary fixed source calculation for the unperturbed system. A **set of**
22 perturbation particle is started at the collision point in the perturbed region and tracked
23 until death. For a perturbation in a smaller portion of the whole domain, the efficiency
24 of the perturbation source method can be improved by using a virtual scattering

1 coefficient or cross section in the perturbed region, forcing collisions. Performance is
2 evaluated by comparing the proposed method to other Monte Carlo perturbation
3 methods. Numerical tests performed for a particle transport in a two-dimensional
4 geometry reveal that the perturbation source method is less effective than the correlated
5 sampling method for a perturbation in a larger portion of the whole domain. However,
6 for a perturbation in a smaller portion, the perturbation source method outperforms the
7 correlated sampling method. The efficiency depends strongly on the adjustment of the
8 new virtual scattering coefficient or cross section.

10 **Keywords:** Monte Carlo; perturbation; fixed source problem; transport equation

11 12 **1. Introduction**

13 Monte Carlo methods have difficulties in calculating the effect of a small
14 perturbation in the system parameters. The effect of a perturbation, of course, can be
15 obtained by performing two independent Monte Carlo calculations and subtracting the
16 estimates of the unperturbed system from those of the perturbed system. A prohibitively
17 huge computational cost would however be required to obtain statistically significant
18 estimates for a small perturbation. The statistical uncertainty of the difference between
19 two independent runs is sometimes comparable with the change of the estimates if the
20 perturbation is small and the computation time short. Thus far, two perturbation
21 calculation methods, the correlated sampling method [1–5] and the differential operator
22 sampling method [4, 6, 7], have been developed to overcome difficulties in the Monte
23 Carlo perturbation calculations. These methods have been widely investigated; their
24 unique advantages and drawbacks have been identified in many publications (e.g.,
25 [8–12]).

26 In the correlated sampling method, the perturbed history is forced to follow the

1 unperturbed one along the same tracks in phase space. It has been found that the
2 correlated sampling method suffers from a large or unbounded variance when the
3 perturbation exceeds a certain limit [4].

4 The differential operator sampling method accumulates a sum of products
5 combining cross section, path segment probabilities, and associated partial derivatives
6 (first order and higher) for all trajectories. The divergence of the variance, which
7 frequently occurs in the correlated sampling method for a larger perturbation, can be
8 circumvented in the differential operator method. However, the differential operator
9 sampling method uses up to the second-order terms in a widely used Monte Carlo code,
10 MCNP [12], and the higher-order terms, beyond the third order, are truncated. A
11 localized and large perturbation would require higher-order terms, truncated in
12 commonly-used differential operator sampling method. As the order becomes higher,
13 the mathematical formulation of the higher-order terms becomes more involved. In
14 addition, many quantities need to be scored during the course of the particle's random
15 walk, making the calculation less efficient. In the Monte Carlo code, MVP, the order of
16 the differential operator method is uniquely expanded to the 8th order [9]. However
17 higher the order is, the differential operator sampling method remains essentially
18 approximate and may be occasionally insufficient for large and localized perturbations.

19 The two Monte Carlo perturbation methods have already been implemented into
20 some Monte Carlo production codes [8, 9, 12–16]. The two Monte Carlo perturbation
21 methods can be applied to perturbation calculations in k_{eff} -eigenvalue problems as well
22 as fixed source problems. In the k_{eff} -eigenvalue problems, the fission source spatial
23 distribution is also perturbed due to the perturbation of system parameters such as cross
24 sections and material density. To estimate the effect of the fission source perturbation,
25 some techniques have been developed and installed into Monte Carlo codes [8, 9, 17].

1 For the fixed source problems, on the other hand, the need to consider the fission source
2 perturbation effect can be avoided.

3 Besides the correlated sampling method and the differential operator method, there
4 exists another perturbation method known as the “perturbation source” method [18–20]
5 in which a separate random walk is performed to follow a “perturbation particle” once a
6 perturbed region is encountered in the original random walk. The perturbation particle
7 explicitly represents the change of the flux due to the perturbation. However, this
8 method is less effective when a large number of collisions occurs in the perturbed
9 region during a history, too many perturbation particles must be followed. On the other
10 hand, if the perturbed region is very small, most of particles pass through the perturbed
11 region without collision and too few perturbation particles are started, which make the
12 perturbation source method less effective than other perturbation techniques. To
13 compensate for the shortcomings of the perturbation source method, Preeg and Tsang
14 [20] proposed a hybrid method that uses the correlated sampling method initially, and
15 then switches to the perturbation source method for the remainder of the history.
16 According to [18, 19], the perturbation source method has been used within the
17 first-order accuracy by neglecting higher-order terms; although it is known that the
18 method can be easily extended to an exact perturbation method [18]. Thus, the formerly
19 proposed perturbation source method only yields an approximate estimate of
20 perturbation.

21 The present paper focuses on the Monte Carlo perturbation method for **particle**
22 **(light or neutron)** transport in a semi-transparent material. The perturbation source
23 method is improved to take into account higher-order terms neglected in the previous
24 studies. This paper proposes a method for improving the effectiveness of the
25 perturbation source method to estimate the variation of flux in problems where the

1 perturbed region covers only a small fraction of the whole domain. The dependence of
 2 the efficiency improvement for a user-specified parameter is investigated. It is shown
 3 that the newly improved perturbation source method outperforms the correlated
 4 sampling method and the differential operator method for such problems in terms of
 5 computation efficiency. The underlying concept of this paper is applicable to other
 6 particle transport calculations. In the sections that follow, the theory and numerical
 7 examples are presented.

9 2. Theory of the improved perturbation source method

10 This section presents a theory of the perturbation method used to calculate the
 11 difference of flux variation caused by the perturbation of system parameters in a fixed
 12 source problem. The theory is already proposed [18, 19] and simple, but it provides an
 13 exact perturbation method that can be performed in the Monte Carlo method. The
 14 unperturbed light transport equation with a fixed source is given by

$$15 \quad \mathbf{H}\phi(\mathbf{r}, \boldsymbol{\Omega}, E) = S(\mathbf{r}, \boldsymbol{\Omega}, E), \quad (1)$$

16 where

$$17 \quad \begin{aligned} & \mathbf{H}\phi(\mathbf{r}, \boldsymbol{\Omega}, E) \\ & \equiv \boldsymbol{\Omega} \cdot \nabla \phi(\mathbf{r}, \boldsymbol{\Omega}, E) + \mu_t(\mathbf{r}, E)\phi(\mathbf{r}, \boldsymbol{\Omega}, E) \\ & - \int_{4\pi} d\boldsymbol{\Omega}' \int dE' \mu_s(\mathbf{r}, \boldsymbol{\Omega}' \rightarrow \boldsymbol{\Omega}, E' \rightarrow E)\phi(\mathbf{r}, \boldsymbol{\Omega}', E'), \end{aligned} \quad (2)$$

18 $\phi(\mathbf{r}, \boldsymbol{\Omega}, E)$ = the unperturbed flux at position \mathbf{r} with energy E and direction $\boldsymbol{\Omega}$,
 19 $S(\mathbf{r}, \boldsymbol{\Omega}, E)$ = the external light source term, μ_t = the total coefficient of absorption and
 20 scattering, μ_s = the scattering coefficient. We suppose that the coefficients in Eq. (2)
 21 are perturbed with the fixed source term being unchanged. Then, the flux is perturbed to
 22 $\phi'(\mathbf{r}, \boldsymbol{\Omega}, E) (\equiv \phi(\mathbf{r}, \boldsymbol{\Omega}, E) + \delta\phi(\mathbf{r}, \boldsymbol{\Omega}, E))$ where $\delta\phi(\mathbf{r}, \boldsymbol{\Omega}, E)$ is the difference of the flux
 23 due to the perturbation. On the other hand, the perturbed flux, $\phi'(\mathbf{r}, \boldsymbol{\Omega}, E)$, obeys the
 24 following perturbed transport equation:

$$25 \quad \mathbf{H}\phi'(\mathbf{r}, \boldsymbol{\Omega}, E) + \Delta\mathbf{H}\phi'(\mathbf{r}, \boldsymbol{\Omega}, E) = S(\mathbf{r}, \boldsymbol{\Omega}, E). \quad (3)$$

1 $\Delta\mathbf{H}\phi(\mathbf{r}, \mathbf{\Omega}, E)$ is described by

$$\begin{aligned}
& \Delta\mathbf{H}\phi(\mathbf{r}, \mathbf{\Omega}, E) \\
& \equiv \Delta\mu_t(\mathbf{r}, E)\phi(\mathbf{r}, \mathbf{\Omega}, E) \\
& - \int_{4\pi} d\mathbf{\Omega}' \int dE' \Delta\mu_s(\mathbf{r}, \mathbf{\Omega}' \rightarrow \mathbf{\Omega}, E' \rightarrow E)\phi(\mathbf{r}, \mathbf{\Omega}', E'),
\end{aligned} \tag{4}$$

3 where $\Delta\mu_t$ and $\Delta\mu_s$ are the differences of the total coefficient and the scattering
4 coefficient due to the perturbation, respectively. Subtracting Eq. (1) from Eq. (3) yields
5 the transport equation for the flux difference $\delta\phi(\mathbf{r}, \mathbf{\Omega}, E)$:

$$\mathbf{H}\delta\phi(\mathbf{r}, \mathbf{\Omega}, E) + \Delta\mathbf{H}\delta\phi(\mathbf{r}, \mathbf{\Omega}, E) = -\Delta\mathbf{H}\phi(\mathbf{r}, \mathbf{\Omega}, E). \tag{5}$$

7 The right-hand side of Eq. (5) represents a source term for this equation and is defined
8 by Eq. (4). To solve Eq. (5), the unperturbed flux $\phi(\mathbf{r}, \mathbf{\Omega}, E)$ on the right-hand side of
9 Eq. (5) needs to be obtained by the unperturbed transport equation, Eq. (1), with the
10 fixed source $S(\mathbf{r}, \mathbf{\Omega}, E)$. Once we know the unperturbed flux and the source term for Eq.
11 (5), the flux difference $\delta\phi(\mathbf{r}, \mathbf{\Omega}, E)$ can be obtained by solving Eq. (5).

12 Formerly, the perturbation source method was used by omitting the second term on
13 the left-hand side of Eq. (5) [18, 19]. However, it is very easy to include this term by
14 transporting perturbation particles in the *perturbed* system, not in the unperturbed
15 system as noted in [18]. This perturbation method that solves Eq. (5) can provide an
16 exact flux difference without approximation. When we apply this perturbation method
17 to a deterministic method, the unperturbed flux distribution is calculated first and then it
18 is stored in a memory or a file. Then, Eq. (5) is solved by reading the unperturbed flux
19 distribution from the file or memory. As can be seen in Eq. (4), the flux is energy- and
20 angular-dependent to estimate the source term in Eq. (5). Thus, if a three dimensional
21 problem with a fine energy group structure is being treated, a huge memory or file
22 storage would be required. We have to note that the source term can be positive and
23 negative, thereby making the flux difference positive and negative as well.

24

1 **3. Monte Carlo algorithm of the perturbation source method**

2 **3.1 Monte Carlo algorithm for calculating flux difference**

3 This section presents a Monte Carlo algorithm to solve the flux difference transport
4 equation, Eq. (5). First of all, a fixed source Monte Carlo calculation is performed to
5 solve Eq. (1), and the unperturbed flux $\phi(\mathbf{r}, \boldsymbol{\Omega}, E)$ is obtained. This calculation is
6 called the “fixed source calculation mode”. Up to this point, this procedure is similar to
7 ordinary fixed source calculations. When a particle undergoes a collision in the
8 perturbed region, the source term for the flux difference equation, Eq. (5), is estimated.
9 The information for the source term is composed of the position, energy, direction, and
10 particle weight. Two methods are available for obtaining the source term. One method
11 is to perform the unperturbed fixed source calculation until a sufficiently large number
12 of collision points are accumulated. After the unperturbed fixed source calculation is
13 completed, the accumulated seven-dimensional data (3 for position, 1 for energy, 2 for
14 direction, and 1 for particle weight) are used for the subsequent flux difference
15 calculation for Eq. (5). This method, however, requires a large storage capacity to store
16 a sufficient amount of source information. This is more serious in the Monte Carlo
17 method since a collision point is defined in the continuous space while the flux is
18 allocated at discrete points in the deterministic methods.

19 Another method, which is adopted in this paper, is a so-called “on-the-fly”
20 technique. When a particle undergoes a collision in the perturbed region in the
21 *unperturbed* system, the fixed source calculation is temporarily suspended. Then, the
22 source term for Eq. (5) is calculated using Eq. (4) and a new particle (perturbation
23 particle), which represents the flux difference, is emitted from the collision point ([how
24 to determine the weight, energy, and direction of the new particle is described below](#)).
25 This process is called the “perturbation calculation mode”. The perturbation particle is

1 tracked using the *perturbed* parameters as defined on the left-hand side of Eq. (5). The
 2 proposed perturbation method can yield the exact values of the flux change on the
 3 grounds that the perturbed parameters are used for tracking the perturbation particle.
 4 After the perturbation particle emitted from the collision point is killed when escaping
 5 from the external boundary or Russian roulette game, the calculation for Eq. (5) is
 6 terminated. Then, [the suspended fixed source calculation is resumed](#) as if nothing had
 7 happened. This process is repeated until desired statistics for the flux difference are
 8 reached.

9 Next, how to define the source term in Eq. (5) in the Monte Carlo method is
 10 discussed. Once a particle with a weight of W undergoes a collision in the perturbed
 11 region in the *unperturbed* system, the calculation mode is switched to the perturbation
 12 calculation mode. The source term in Eq. (5) is defined as follows.

13 (1) Source term caused by the perturbation of the total coefficient

14 The first term on the right-hand side of Eq. (4) is caused by the perturbation of the
 15 total coefficient. This term is represented by

$$16 \quad W_t = -\Delta\mu_t(\mathbf{r}, E) \frac{W}{\mu_t(\mathbf{r}, E)}. \quad (6)$$

17 A new perturbation particle with a weight of W_t is emitted from the collision point.

18 The direction and energy of the new particle are unchanged from the colliding particle.

19 If $\Delta\mu_t > 0$, the weight W_t is negative.

20 (2) Source term due to the perturbation of the scattering coefficient

21 The second term on the right-hand side of Eq. (4) is caused by the perturbation of
 22 the scattering coefficient. This source term is composed of the perturbation of the total
 23 scattering coefficient and the scattering angle and energy distribution function. This
 24 source term is obtained by the following steps.

25 1) The direction Ω' and energy E' after the scattering are sampled from the

1 probability density function of the *unperturbed* scattering cross section
 2 $\mu_s(\mathbf{r}, \mathbf{\Omega} \rightarrow \mathbf{\Omega}', E \rightarrow E')$.

3 2) The source term due to the perturbation of the total scattering coefficient is
 4 obtained with

$$5 \quad W_s = (\mu_s^p(\mathbf{r}, E) - \mu_s(\mathbf{r}, E)) \frac{W}{\mu_t(\mathbf{r}, E)}, \quad (7)$$

6 where

$$7 \quad \mu_s(\mathbf{r}, E) \equiv \int_{4\pi} d\mathbf{\Omega}' \int_0^\infty dE' \mu_s(\mathbf{r}, \mathbf{\Omega} \rightarrow \mathbf{\Omega}', E \rightarrow E'), \quad (8)$$

8 and the superscript p denotes that the quantity is for the perturbed system. Note that the
 9 integrals in Eq. (8) are carried out with respect to the angle and energy after scattering.

10 3) The source term due to the perturbation of the scattering angle and energy
 11 distribution is obtained by

$$12 \quad W_a = \frac{P^p(\mathbf{\Omega}', E') - P(\mathbf{\Omega}', E')}{P(\mathbf{\Omega}', E')} \mu_s^p(\mathbf{r}, E) \frac{W}{\mu_t(\mathbf{r}, E)}, \quad (9)$$

13 where $P(\mathbf{\Omega}', E')$ is the probability density function of the direction $\mathbf{\Omega}'$ and the
 14 energy E' after scattering in the unperturbed system. [Note that Eq. \(9\) is simply
 15 written and it should be modified to use the formatting of the atomic or nuclear data.](#)

16 4) A new perturbation particle with a weight of $(W_s + W_a)$ is emitted from the
 17 collision point. The perturbation particle's direction and energy are $\mathbf{\Omega}'$ and E' ,
 18 respectively.

19 Consequently, the two perturbation particles, which are the sources for the flux
 20 difference calculation, are emitted from every collision point, and they are tracked until
 21 their deaths. The score of the perturbation particles [divided by the total sum of starting
 22 particles' weights from the source](#) represents the perturbed flux $\delta\phi(\mathbf{r}, \mathbf{\Omega}, E)$. The two
 23 perturbation particles are independent and can be emitted in no particular order. A
 24 schematic flow chart of this perturbation method is shown in Fig. 1. When the two

1 perturbation particles emitted from the collision point are **both** killed, the fixed source
2 calculation for Eq. (1) resumes from the collision point. The weights of the perturbation
3 particles for the flux difference calculation are in general smaller than those of the fixed
4 source calculation for Eq. (1) in the unperturbed system, depending on the perturbation
5 and colliding particle's weight. The lower weight threshold for Eq. (5) should be
6 smaller than the one of the fixed source calculation for Eq. (1) **if the Russian roulette**
7 **game is applied.**

8 [Fig.1]

9 **As new features of this paper, the performance of the perturbation source method is**
10 **compared with other Monte Carlo perturbation methods and a method for improving the**
11 **efficiency is proposed below.**

12

13 **3.2 Improvement of the perturbation source method**

14 As shown in Fig. 1, the perturbation calculation does not start unless the particle
15 undergoes a collision within the perturbed region. Even when the particle enters the
16 perturbed region, the particle that passes through the region without collision does not
17 initiate a perturbation particle. In problems where the perturbed region covers only a
18 small fraction of the whole domain, perturbation particles are rarely emitted, which
19 makes the perturbation calculation less effective. For improving the efficiency of the
20 perturbation source method, a virtual scattering coefficient is added to the perturbed
21 region. The total coefficient μ_t is increased by a factor of $C (>1)$. An increased pseudo
22 total coefficient,

$$23 \mu_t^* = C \cdot \mu_t, \quad (10)$$

24 is assigned to the perturbed region. The increased pseudo total coefficient is used for the
25 calculation for the fixed source calculation mode. This method is similar to the
26 Woodcock delta tracking [21] that is used as an efficient algorithm for free path

1 sampling in heterogeneous media. When a particle undergoes a collision within the
 2 perturbed region having the pseudo total coefficient μ_t^* , a perturbation particle is
 3 emitted from the collision point. The starting weight of the perturbation particle is
 4 adjusted to compensate for the biased total coefficient:

$$5 \quad W_t' = \frac{W_t}{C}, \quad (11)$$

$$6 \quad W_s' + W_a' = \frac{W_s + W_a}{C}, \quad (12)$$

7 where W_t , W_s , and W_a are defined by Eqs. (6), (7), and (9), respectively. After the
 8 perturbation particles are killed, the perturbation calculation mode is terminated. Then,
 9 the fixed source calculation mode is resumed, and a pseudo random number ξ between
 10 0 and 1 is generated. If the random number meets the criteria:

$$11 \quad \xi < \frac{\mu_t}{\mu_t^*} \left(= \frac{1}{C} \right), \quad (13)$$

12 the virtual collision in the fixed source calculation mode is accepted as the real collision.
 13 If not, the virtual collision is rejected and the random walk continues with the direction,
 14 energy, and weight being left unchanged. Whether the virtual collision is accepted or
 15 not, the next free path within the perturbed region is sampled with μ_t^* .

16

17 **4. Numerical tests for the perturbation source method**

18 **4.1 Overview of the numerical tests**

19 Numerical tests for the proposed Monte Carlo perturbation method are performed
 20 for a two-dimensional 2 cm \times 2 cm homogeneous rectangular domain. Following the
 21 customary procedure of light transport calculations, the energy dependence is neglected
 22 and the scattering angular distribution function is unchanged by the perturbation. The
 23 Henyey-Greenstein function [22, 23], which is commonly used in light transport
 24 calculations, is chosen for the scattering angular distribution function:

$$25 \quad f(\mathbf{r}, \boldsymbol{\Omega}' \rightarrow \boldsymbol{\Omega}) = \frac{1}{4\pi} \frac{1 - g^2}{(1 + g^2 - 2g \cos \theta)^{3/2}}, \quad (14)$$

1 where θ is the angle between Ω' and Ω , and g is the anisotropy factor. The optical
 2 parameters of the unperturbed system are:

$$3 \quad \mu_s = 10 \text{ cm}^{-1}, \quad \mu_a = 0.5 \text{ cm}^{-1}, \quad \text{and } g = 0.9,$$

4 where μ_a = absorption coefficient and $\mu_t = \mu_a + \mu_s = 10.5 \text{ cm}^{-1}$.

5 As discussed above, the efficiency of the perturbation source method depends on
 6 the fraction of the perturbed region. First, the perturbation source method is tested for a
 7 perturbation in a larger portion of the whole domain. Then, a perturbation in a smaller
 8 portion is tested.

10 **4.2 Perturbation in a large portion**

11 The absorption coefficient or scattering coefficient is changed in the $1.6 \text{ cm} \times 1.6$
 12 cm region as shown in Fig. 2. A beam source perpendicular to the “Side 3” is placed at
 13 the center of the “Side 3” in Fig. 2. The incident beam is perpendicular to the “Side 3”.

14 When a particle with a weight of W leaves one of four sides, the boundary measurement
 15 of the particle,

$$16 \quad W \cdot (\mathbf{n} \cdot \Omega), \quad (15)$$

17 is scored where Ω = particle’s direction and \mathbf{n} = unit outward vector normal to the
 18 boundary surface, and the boundary is considered transparent and non-reflecting. The
 19 exitance on a side is estimated as

$$20 \quad P_d = \frac{1}{N} \sum_i W_i \cdot (\mathbf{n} \cdot \Omega_i), \quad (16)$$

21 where W_i = i th particle’s weight leaving the side, and i is summed over all particles
 22 leaving the side, and N = the total number of particles emitted from the source.

23 [Fig. 2]

24 Two perturbations are considered for the numerical tests. In the first one, the
 25 absorption coefficient in the perturbed region is increased by 20% (i.e., $+0.1 \text{ cm}^{-1}$). In
 26 the second one, the scattering coefficient is increased by 20% (i.e., $+2.0 \text{ cm}^{-1}$). To
 27 compare the perturbation source method with other perturbation techniques, the

1 correlated sampling method, the first-order differential operator method, and the
 2 second-order differential method are used.

3 In the correlated sampling method used in this paper, the perturbed history is forced
 4 to follow the unperturbed one along the same track. When a particle having a **weight** of
 5 W flies a distance s and undergoes a collision in the perturbed region, the weight of the
 6 perturbed history after the collision is [24]

$$7 \quad W \frac{\mu'_t e^{-\mu'_t s}}{\mu_t e^{-\mu_t s}} \cdot \frac{\mu'_s / \mu'_t}{\mu_s / \mu_t} \cdot \frac{\mu_s}{\mu_t} = W \cdot e^{-\Delta\mu_t s} \frac{\mu'_s}{\mu_t}, \quad (17)$$

8 where the prime denotes the perturbed coefficient and $\Delta\mu_t = \mu'_t - \mu_t$.

9 The differential operator method estimates the perturbed exitance **with the Taylor**
 10 **series expansion** when an optical parameter p changes by Δp :

$$11 \quad \Delta P_d = \frac{\partial P_d}{\partial p} \Delta p + \frac{1}{2} \frac{\partial^2 P_d}{\partial p^2} \Delta p^2 + \dots \quad (18)$$

12 **Cross terms on the second derivative [25] are neglected because the material is single or**
 13 **the perturbation merely changes the density in the examples of this paper.**

14 In the first-order differential operator method, the first-derivative of P_d with respect to
 15 μ_a and μ_s in the perturbed region are respectively [26]:

$$16 \quad \frac{\partial P_d}{\partial \mu_a} = -\frac{1}{N} \sum_i W_i \cdot (\mathbf{n} \cdot \boldsymbol{\Omega}_i) S_i, \quad (19)$$

$$17 \quad \frac{\partial P_d}{\partial \mu_s} = \frac{1}{N} \sum_i W_i \cdot (\mathbf{n} \cdot \boldsymbol{\Omega}_i) \left(\frac{M_i}{\mu_s} - S_i \right), \quad (20)$$

18 where $S_i =$ sum of the path lengths in the perturbed region for i th detected particle,
 19 and $M_i =$ number of collisions in the perturbed region for i th detected particle. S_i and
 20 M_i are accumulated during the course of the random walk in the fixed source Monte
 21 Carlo calculation with the unperturbed optical parameters. Similarly, the
 22 second-derivative of P_d with respect to μ_a and μ_s in the perturbed region are
 23 respectively [26]:

$$\frac{\partial^2 P_d}{\partial \mu_a^2} = \frac{1}{N} \sum_i W_i \cdot (\mathbf{n} \cdot \boldsymbol{\Omega}_i) S_i^2, \quad (21)$$

$$\frac{\partial^2 P_d}{\partial \mu_s^2} = \frac{1}{N} \sum_i W_i \cdot (\mathbf{n} \cdot \boldsymbol{\Omega}_i) \left(-\frac{M_i}{\mu_s^2} + \left(\frac{M_i}{\mu_s} - S_i \right)^2 \right). \quad (22)$$

(1) Perturbation of absorption coefficient

The change of P_d due to the change of the absorption coefficient by +20% are obtained by the four perturbation methods (correlated sampling, perturbation source, first-order, and second-order differential operator methods) and are shown in Table 1-a. In addition to the Monte Carlo perturbation methods, the change of P_d is obtained by the difference between two independent runs before and after the perturbation. For the perturbation source method, the factor C defined in Eq. (10) is chosen as $C = 1$ and 4. Throughout this paper, the change of P_d calculated by the perturbation source method agrees with that by the correlated sampling method within 2 standard deviations. The results obtained by the first-order differential operator method significantly differs from other methods. However, the second-order differential operator method performs much better than the first order.

Table 1-b compares the relative figure-of-merit (FOM) defined by

$$\text{FOM} = \frac{1}{s^2 T}, \quad (23)$$

where s = one standard deviation of absolute uncertainty and T = computation time. The FOM's are normalized with respect to the correlated sampling. The perturbation source method is less effective compared to other perturbation methods regardless of the factor C . Furthermore, the computation efficiency of the perturbation source method decreases with the factor C , which is contrary to expectation. The additional computational cost for handling more perturbation particles may not be worth the gain of reducing the uncertainty for this problem.

[Table 1-a], [Table 1-b]

1 (2) Perturbation of scattering coefficient

2 The Monte Carlo perturbation calculations due to the perturbation of the scattering
3 coefficient have larger variances than the absorption coefficient. In the first-order
4 differential operator method, for example, **this is** because two terms, in the parentheses
5 in Eq. (20), M_i/μ_s and S_i , almost cancel each other. The change of P_d due to the
6 change of the scattering coefficient by +20% and the relative FOMs are shown in
7 Tables 2-a and 2-b, respectively. In this case, the second-order differential operator
8 method does not perform as well as with the perturbation of the absorption coefficient.
9 Higher-order derivatives would be required to obtain more accurate estimates using the
10 differential operator method. The FOMs of the perturbation source method for the
11 scattering coefficient are much worse than for the absorption coefficient. The factor C
12 does not affect the efficiency of the perturbation source method unlike the perturbation
13 of the absorption coefficient.

14 As a conclusion, the source perturbation method can certainly yield an exact
15 estimate of the perturbation. However, for a perturbation in a larger portion of the whole
16 domain, the efficiency is inferior to other Monte Carlo perturbation methods.

17 [Table 2-a], [Table 2-b]

18 **4.3 Perturbation in a small portion**

19 The absorption coefficient or scattering coefficient is changed in the $0.0833 \text{ cm} \times$
20 0.0833 cm region as shown in Fig. 3. **Again, a beam source perpendicular to the “Side**
21 **3” is placed at the center of the “Side 3”**. The perturbed area within the whole domain
22 accounts for 0.17% of the whole domain. **First, a smaller perturbation is added to the**
23 **perturbed region**. According to [4], the correlated sampling method suffers from a large
24 or unbounded variance for a large perturbation. Therefore, **a larger perturbation is also**
25 **tested** to compare the efficiency of the perturbation source method to the correlated
26 sampling method.

(1) Smaller perturbation of absorption coefficient

The absorption coefficient in the perturbed region is increased by 20% (i.e., $+0.1 \text{ cm}^{-1}$). The correlated sampling method, the perturbation source method ($C = 1, 4,$ and 32), the first-order differential operator method, and the second-order differential method are performed for the perturbation calculation, the change of P_d and their relative FOMs are shown in Tables 3-a, and 3-b, respectively. For this perturbation, the estimates of the first-order differential operator method agree with other perturbation methods within 2%, which is much better than the results for the larger perturbation.

The efficiency of the perturbation source method with $C = 1$ is improved in the two sides and worsened in the remaining two sides compared with other perturbation methods. The efficiency of the perturbation source method becomes better as C increases. By adjusting the factor C , the perturbation source method can be superior to other Monte Carlo perturbation techniques.

[Table 3-a], [Table 3-b]

(2) Larger perturbation of absorption coefficient

The absorption coefficient in the perturbed region is increased by 300% (i.e., $+1.5 \text{ cm}^{-1}$). The results are shown in Tables 4-a, and 4-b. The tendency of the relative FOMs in Table 4-b is almost the same as the smaller perturbation in Table 3-b.

[Table 4-a], [Table 4-b]

(3) Smaller perturbation of scattering coefficient

The scattering coefficient in the perturbed region is increased by 30% (i.e., $+3.0 \text{ cm}^{-1}$). The results are shown in Tables 5-a, and 5-b. The perturbed source method with $C = 1$ is approximately half as effective as the correlated sampling method. However, the efficiency of the perturbed source method increases with the factor C . When $C = 32$, the perturbation source method outperforms the correlated sampling method by a factor

1 of 7. The perturbation source method can achieve a higher efficiency than other
2 perturbation methods by adjusting the factor C .

3 [Table 5-a], [Table 5-b]

4 (4) Larger perturbation of scattering coefficient

5 The scattering coefficient in the perturbed region is increased by 200% (i.e., +20.0
6 cm^{-1}). The results are shown in Tables 6-a, and 6-b. For such a larger perturbation of the
7 scattering coefficient, the correlated sampling method incurs a larger variance, which
8 can be observed by comparing the FOMs between the correlated sampling method and
9 the differential operator method. Thus, the perturbation source method and the
10 differential operator method exhibit relatively better performance than the correlated
11 sampling method. The improvement of the efficiency in the perturbation source method
12 is more remarkable than in the smaller perturbation. When $C = 32$, the perturbation
13 source method is about 50 times more efficient than the correlated sampling method.

14 [Table 6-a], [Table 6-b]

15 **4.4 Perturbation in an anisotropy factor**

16 In the next example, the anisotropy factor of the Henyey-Greenstein function,
17 which is defined in Eq. (14), is perturbed in the perturbed region in Fig. 3. The
18 correlated sampling method, the perturbation source method ($C = 1, 4, \text{ and } 32$), the
19 first-order differential operator method, and the second-order differential method are
20 tested for the perturbation calculation.

21 In the perturbation source method, when a particle having a weight of W undergoes
22 a collision within the perturbed region, a perturbation particle is emitted from the
23 collision point. The scattering angle θ for the perturbation particle is sampled using Eq.
24 (14). The weight of the perturbation particle emitted from the collision point is:

$$25 \quad W_a = \frac{f(\theta, g') - f(\theta, g)}{f(\theta, g)} \mu_s^p \frac{W}{\mu_t}, \quad (24)$$

1 where g' = the perturbed anisotropy factor, and

$$2 \quad f(\theta, g) = \frac{1}{4\pi} \frac{1 - g^2}{(1 + g^2 - 2g \cos \theta)^{3/2}}. \quad (25)$$

3 In the correlated sampling method, when a particle having a weight of W flies a
4 distance s and undergoes a collision in the perturbed region, the weight of the perturbed
5 history after the collision is

$$6 \quad W \cdot e^{-\Delta\mu_t s} \frac{\mu_s}{\mu_t} \cdot \frac{f(\theta, g')}{f(\theta, g)}, \quad (26)$$

7 where θ = the scattering angle for the perturbed and unperturbed histories after the
8 collision.

9 In the differential operator method, the first- and the second-derivative of P_d with
10 respect to the anisotropy factor g in the perturbed region are respectively [26]:

$$11 \quad \frac{\partial P_d}{\partial g} = \frac{1}{N} \sum_i W_i \cdot (\mathbf{n} \cdot \boldsymbol{\Omega}_i) G_{1i}, \quad (27)$$

$$12 \quad \frac{\partial^2 P_d}{\partial g^2} = \frac{1}{N} \sum_i W_i \cdot (\mathbf{n} \cdot \boldsymbol{\Omega}_i) (G_{1i}^2 + G_{2i}), \quad (28)$$

13 where

$$14 \quad G_{1i} = \sum_j \frac{1}{f(\theta_j, g)} \frac{\partial f(\theta_j, g)}{\partial g}, \quad (29)$$

$$15 \quad G_{2i} = \sum_j \frac{\partial}{\partial g} \left(\frac{1}{f(\theta_j, g)} \frac{\partial f(\theta_j, g)}{\partial g} \right), \quad (30)$$

16 and the summation symbols for j denote the sum for all collisions in the perturbed
17 region.

18 The perturbation calculations are performed when the anisotropy factor g is
19 changed from 0.9 to 0.895. The change of P_d and their relative FOMs are shown in
20 Tables 7-a, and 7-b, respectively. The perturbed source method with $C = 1$ is as
21 effective as other perturbation methods for this perturbation. However, the efficiency of
22 the perturbation source method increases with the factor C . Tables 8-a and 8-b show the
23 results when the perturbation of g is much larger (from 0.9 to 0.6). For the perturbation
24 of g , the perturbation source method outperforms other perturbation methods regardless

1 of the factor C .

2 [Table 7-a], [Table 7-b], [Table 8-a], [Table 8-b]

3 **4.5 Perturbation for Multi-group Neutron Transport in a heterogeneous geometry**

4 The perturbation source method is applied to perturbation calculations for
5 multi-group neutron transport in a heterogeneous geometry. The geometry for the
6 perturbation calculations is a two-dimensional right square having a checkerboard
7 pattern array of light water and graphite as shown in Fig. 4. The calculations use 3
8 energy group constants that are prepared with the standard reactor analysis code SRAC
9 [27]. The constants are listed in Table 9. The scattering is assumed to be isotropic. A
10 line neutron beam in the 1st energy group perpendicular to the “Side 3” enters from the
11 center of the “Side 3”. As the perturbation added to this configuration, the water density
12 of the perturbed region decreases by 80%. In the same manner as in the numerical
13 examples shown above, the changes of the neutron currents in the 3rd energy group (i.e.,
14 thermal neutron) on the four outer boundaries are calculated with the three perturbation
15 methods. The change of the thermal neutron currents and their relative FOMs are shown
16 in Tables 10-a, and 10-b, respectively. Among the perturbation methods tested in this
17 paper, the computation efficiency is maximized when the perturbation source method
18 with $C \approx 30$ is used. The tendency for this neutron transport in the heterogeneous
19 geometry is the same as the numerical examples for the light transport.

20 [Fig. 4][Table 9][Table 10-a][Table 10-b]

21 **5. Conclusions**

22 The present paper has proposed an exact Monte Carlo perturbation method for
23 fixed source problems, which is dubbed the “perturbation source method”. **This paper is**
24 **actually an improvement over a previously proposed version of the perturbation source**
25 **method.** In the previous studies for the perturbation source method, the higher-order
26 perturbation has been neglected and the accuracy has been limited within the first-order

1 perturbation. On the other hand, the perturbation source method in this paper solves
2 explicitly and exactly the transport equation for the flux difference without
3 approximation by tracking “perturbation particles” in the perturbed system. This method
4 employs a quite different concept from the well-known perturbation methods such as
5 the correlated sampling method and the differential operator method. This method
6 requires the flux in the unperturbed system as its source term. The unperturbed flux is
7 provided by an “on-the-fly” technique during the course of the ordinary fixed source
8 calculation for the unperturbed system. Then, a perturbation particle that started from
9 the collision point in the perturbed region is tracked until its death.

10 If the perturbed region covers a larger portion of the whole domain, too many
11 perturbation particles have to be tracked, which makes the perturbation source method
12 less effective than the correlated sampling method. On the other hand, if the perturbed
13 region covers only a smaller portion of the whole domain, too few perturbation particles
14 are started. For a perturbation in a smaller portion, the efficiency of the perturbation
15 source method can be improved by adding a virtual scattering coefficient to the
16 perturbed region, **forcing** collisions in the perturbed region.

17 The numerical tests are performed for a **particle** transport in a two-dimensional
18 semi-transparent material. The numerical tests in this paper compare the perturbation
19 source method with the correlated sampling method, the first-order differential operator
20 method, and the second-order differential operator method. The perturbation source
21 method is less effective than the correlated sampling method for a perturbation in a
22 larger portion of the whole domain. However, the perturbation source method
23 outperforms other perturbation methods in situations where the perturbed region covers
24 only a smaller portion of the whole domain. The improvement by the perturbation
25 source method depends on the added virtual scattering coefficient **or cross section** and

1 on how large the perturbation is. For a large perturbation, the correlated sampling
2 method suffers from a large variance. In such a case, the performance of the
3 perturbation source method is relatively superior to the correlated sampling method.
4 The efficiency of the perturbation source method depends strongly on the adjustment of
5 the virtual scattering coefficient or cross section added to the perturbed region. As a
6 general rule, the efficiency increases with the virtual scattering coefficient added.

7 There still remain some works to be done in the future. The application to the
8 continuous-energy physics is one of future works. The optimization of the factor C for
9 increasing the number of collisions in a perturbed region may also be desirable. The
10 proposed method can be straightforwardly applied to k_{eff} -eigenvalue problems unless the
11 fission source distribution is changed by a perturbation. However, a new algorithm
12 should be invented to take into account the fission source perturbation.
