Abstract

63

71

81

64 Wild Japanese macaques (Macaca fuscata Blyth) living in the highland and 65 lowland areas of Yakushima are known to have different diets, with highland 66 individuals consuming more leaves. We aim to clarify whether and how these 67 differences in diet are also reflected by gut microbial composition and 68 fermentation ability. Therefore, we conduct an in vitro fermentation assay using 69 fresh feces from macaques as inoculum and dry leaf powder of Eurya japonica 70 Thunb. as a substrate. Fermentation activity was higher for feces collected in the highland, as evidenced by higher gas and butyric acid production and lower pH. 72 Genetic analysis indicated separation of highland and lowland in terms of both 73 community structure and function of the gut microbiota. Comparison of feces and 74 suspension after fermentation indicated that the community structure changed 75 during fermentation, and the change was larger for lowland samples. Analysis of 76 the 16S rRNA V3-V4 barcoding region of the gut microbiota showed that 77 community structure was clearly clustered between the two areas. Furthermore, 78 metagenomic analysis indicated separation by gene and pathway abundance 79 patterns. Two pathways (glycogen biosynthesis I and D-galacturonate degradation I) were enriched in lowland samples, possibly related to the 80 fruit-eating lifestyle in the lowland. Overall, we demonstrated that the more 82 leaf-eating highland Japanese macaques harbor gut microbiota with higher leaf 83 fermentation ability compared to the more fruit-eating lowland ones. Broad, 84 non-specific taxonomic and functional gut microbiome differences suggest that 85 this pattern may be driven by a complex interplay between many taxa and pathways rather than single functional traits. 86

Keywords: diet, *in vitro* fermentation assay, meta-16S analysis, digestion, generalists

## Introduction

There are three steps in feeding—searching, processing and digestion—and animals adapt in various ways to maximize nutritional intake and/or minimize intake of toxic compounds at each step. Many animal traits, including locomotion [1], morphology [2], vision [3], gustation [4], and digestion enzymes [5] are, at least partly, a result of this adaptation process, and some of these traits are genetically fixed. While specialization to a particular food type opens up normally inaccessible resources [6], such specialization may, on the other hand, limit overall resource range [7]. Since environmental fluctuations can occur at much shorter time scales compared to adaptive evolution, a generalist strategy may require sufficient flexibility to respond to rapidly changing food conditions [8]. Flexibility can, for instance, be achieved by behavioral adaptation, including changes in activity budget [9], ranging [10], and feeding techniques [11], which have been intensively studied among large-brained, behaviorally flexible generalist animals such as primates [12]. These studies mainly focused on the question of how such behavioral adjustments can increase net food intake.

Recently, as another class of feeding-related flexible adaptations, much attention has been given to the role of the gut microbiome. A typical human individual harbors 10-100 trillion symbiotic microorganisms, the majority of which are gut microbes [13]. Human gut microorganisms are estimated to possess 3.3 million non-redundant genes [14], compared to only around 22,000 genes found in the human genome [15]. Host and microbial symbiont genomes often have

complementary roles in digestion [16]. Cellulose, xylan, and many other polysaccharides are fermented by gut microbes to produce short-chain fatty acids (SCFA), an important energy source for vertebrates [17]. In fact, energy gain through SCFAs is estimated to reach as high as 10% in humans [18] and 31% in a non-human primate species [19]. Furthermore, the genomic diversity of gut microbes among different hosts is much larger than that for the hosts themselves [13], which allows gut microbiota to respond more quickly to environmental fluctuations than their hosts. Another function of the gut microbe is detoxification, i.e. degradation of a plant's toxic and anti-nutritional compounds [20, 21].

Enabled by the development of next-generation sequencing techniques, a rapidly increasing number of studies on the flexibility of the gut microbiome have been published [22]. Many of these studies sequence hypervariable regions of the microbial 16S rRNA gene to assess the taxonomic composition of any given gut community. Community composition can change flexibly with regard to habitat [23-25], age and sex of the host [26, 27], social contact with other animals [28], and season [29-31]. Observational studies of wild populations [32] as well as feeding experiments on captive animals [33] show that the gut microbiome composition adjusts flexibly in response to changes in diet. However, data on community composition is often difficult to link directly to function because many functional genes, including those involved in digestion, are shared across diverse microbial groups [34]. As a result, even though the feeding behavior of non-human primates has been studied in detail, there are few studies, as described below, that clarified the digestive effectiveness of the gut microbiota of wild animals in a direct, straightforward experimental setting.

One way to reveal the specific gut microbiome adaptations is to study the presence and/or expression patterns of functional genes through metagenomic and metatranscriptomic analyses [16, 35]. Combined with metabolomic analysis [36], this approach can enable researchers to track the metabolic pathways involved in digesting specific foods into absorbable nutrients, thus providing a deeper understanding of the role of gut microbes in these processes at the molecular level. However, each food contains various nutrients and toxins, and numerous microbial species with large numbers of genes are involved in their digestion. Data obtained by these omics approaches are thus immense and complex; consequently, extracting system-level insights on the interplay between hosts and their microbial symbionts can be a considerable challenge [34].

Another way to answer an ecologically important, simple question on the effectiveness of the gut microbe in food digestion is *in vitro* fermentation assay [37]. In such assays, live gut microbes contained in fresh feces of animals are used as inoculum with a specific food as a substrate, which is subsequently fermented under *in vitro* conditions (e.g. anaerobic and 37°C). If one type of microbial community is more efficient at fermenting the substrate than others, the overall fermentation activity, such as gas or SCFA production, is expected to be larger. While this method is an established practice in the area of animal husbandry, it is rarely used in wildlife studies. Indeed, previous work on non-human primates has so far been mostly limited to zoo animals [38-41], with the exception of a single study revealing the fermentation ability of plant gum by the gut microbiota of wild chimpanzees [42]. These studies on captive animals found that the relationship between diet and fermentation ability was complex

and non-specific. However, gut microbiome composition can be significantly modified under captivity [43, 44], and recent studies also highlighted the importance of study *in natura*, or in natural environments [45]. Thus, applying *in vitro* fermentation to wild animals *in natura* provides a unique opportunity to study microbiome-related fermentation responses under natural conditions.

The subject of this study, the Japanese macaque (*Macaca fuscata* Blyth), is an ideal species for studying the digestive role of the gut microbiome in a fluctuating environment, since they modify their diet in response to regional and seasonal variations in food availability [46, 47]. In our study site, Yakushima, there is an elevational gradient in fruit production [48]: while the main foods in the fruit-poor highland are fiber-rich foods, such as mature leaves [49], diet in the fruit-rich lowland features more fruits and seeds [50]. These two areas are only about 7 km apart and genetic variation between macaque populations is generally low [51]. Therefore, non-genetic, flexible adjustments are required to survive under the differing food conditions provided by these two contrasting habitats. Since macaques are habituated to human presence in many places in Yakushima [52], the collection of fresh feces is feasible. To further minimize disturbance of the fecal microbiota, *in vitro* fermentation assays can be performed directly on-site at a research station of Kyoto University.

In this study, we examined the hypothesis that the gut microbiome of a generalist host is shaped by the host's flexible feeding behavior and contributes to digestion in a food-type-specific manner. In particular, we tested the prediction that the gut microbiome of the more leaf-eating highland macaques is more capable of fermenting leaves than that of the more fruit-eating lowland macaques. We evaluated the fermentation ability by quantifying gas and SCFA

production in an *in vitro* fermentation assay. Furthermore, we conducted genetic analyses of the fecal samples used in the fermentation assay to better understand which microbial taxa and genes might be responsible for the observed differences in fermentation ability. To this end, we first conducted a meta-16S rRNA gene analysis to determine gut microbiome community profiles in both the highland and lowland, which allowed us to examine whether community composition significantly differs between regions and to identify differentially abundant taxa for each region. We also compared between feces and corresponding suspension samples after fermentation to reveal the changes in the community structure during the assay. Subsequently, we conducted a complementary whole-genome shotgun analysis of the fecal samples to additionally examine functional differences (i.e. in terms of gene and pathway composition). Apart from investigating broad functional differences, we also specifically compared the abundance of 37 genes known to be involved in fermentation. These genes participate in most upstream and downstream stages of the synthesis of SCFAs from polysaccharides.

Methods

205 Study sites

Yakushima is an island in southern Japan (30 °N, 131 °E) with an area of 503 km², with the highest peak being 1936 m in elevation. In the lowland, warm temperate evergreen broad-leaved trees, such as *Castanopsis cuspidata*, *Quercus salicina*, and *Distylium racemosum*, mix with subtropical plants. In the highland, warm-temperate evergreen broad-leaved trees, such as *Q. acuta*, *Q. salicina*, and *D. racemosum*, are interspersed with conifers (including

Cryptomeria japonica, Abies firma, and Tsuga sieboldii). Further details of the study site are described in Hanya et al. [48].

## Study subjects

The subjects of this study, Japanese macaques, have a home range of ca 0.5-1 km² [53] and their daily path length is 2.2-2.6 km [54]. The collection sites in the highland and lowland were more than 3 km apart from each other, so the two sites were used by different groups. In May, when we collected samples for this study, the main foods were reported to be sapfruits of *Myrica rubra* in the lowland and mature leaves of *Symplocos myrtacea* and *Eurya japonica* in the highland [49, 50], which was consistent with our *ad libitum* observation at the time of collection. Neutral detergent fiber content is higher for leaves of *S. myrtaceae* (34.1%) and *E. japonica* (50.8%) than the pulp of *M. rubra* (22.4%) [55].

## Sample collection

On May 22-24, 2016, we collected fresh feces of wild Japanese macaques in the eastern and western highland (730-1330 m a.s.l.; N=12), as well as the western lowland (150-190 m a.s.l.; N=15), of Yakushima (Fig. 1). Defecation was directly observed for the majority of samples, and in all other cases, feces were judged to be fresh (<1 h defecation) because a monkey group was still in the proximity and the surface of the feces showed moistness. During sampling, we first collected a small amount of fecal materials with a cotton swab and kept it in a 2 mL tube filled with RNAlater [56]. To avoid environmental contamination, these genetic samples were collected only from the inner part of the feces, which did not touch the soil. One sample was collected for genetic analysis but could not

be included as an inoculum of the subsequent fermentation assay. We then put all remaining fecal material in a sealed plastic bag, which was semi-vacuumized using a kitchen vacuumizer. The plastic bags were labelled and kept in a jar filled with blue ice. We recorded the sampling locations with a GPS device (GPSMAP 60CSx ®Garmin) and brought the samples to the field station of the Wildlife Research Center of Kyoto University in Nagata village within four hours of sample collection.

In vitro fermentation assay

In the laboratory, one part of the fecal samples was mixed with four parts of McDougall's buffer (ingredients (g/L): NaHCO<sub>3</sub> (9.8), Na<sub>2</sub>HPO<sub>4</sub>·2H<sub>2</sub>O (2.44), KCI (0.57), NaCl (0.47), MgSO<sub>4</sub>·7H<sub>2</sub>O (0.12), CaCl<sub>2</sub>·2H<sub>2</sub>O (0.16)) which was pre-heated at 39°C and saturated with CO<sub>2</sub> gas. We confirmed the pH of the buffer before use as 6.8. We squeezed the mixture through two layers of sterile gauzes to remove large particles in the feces. We subsampled 5 mL of the filtrate, then centrifuged it at 2,600 x g for 5 min at 4°C. The supernatant was stored at -30°C for subsequent measurement of SCFA at time "zero" of the incubation. However, we mistakenly neglected to collect two samples from highland and those seven from lowland, which were therefore excluded from the SCFA measurement. As a substrate, leaves of *Eurya japonica* Thunb. were previously collected in Inuyama city, central Japan. We chose this species because the macagues in both highland and lowland eat this [49]. The leaves were dried at 40°C and then ground by a mill (Wonder Blender WB-1 ®Osaka Chemical) before use. A portion of the filtrate (100 ml) and one gram dry weight of powdered *E. japonica* leaves were poured into a serum bottle. Then, the bottles

were closed with butyl rubber stoppers and aluminum seals after replacing the head-space gas with 100% CO<sub>2</sub>. Bottles were placed in a water bath at 37°C with continuous shaking for 24 h. Gas production, an indicator of fermentation activity, was measured at 6 h, 12 h, 18 h and 24 h of incubation by displacing a plunger of a 10-ml glass syringe in a manner similar to the method established by Blümmel and Ørskov [57]. After 24 h, the pH of inoculum was measured and additional samples were collected for DNA analysis of the suspension after fermentation (SAF, hereafter). Then, it was centrifuged at 2,600 x g for 5 min at room temperature, and the supernatant was collected for SCFA analysis.

## SCFA analysis

Analysis of SCFA was conducted by TechnoPro R&D, Inc., Nagoya, Japan. The samples were centrifuged at 10,000 rpm for 5 min at 4°C, and the supernatant was filtered with 0.45 µm PVDFfilter (Millex-HV filter, Merk Millipore). The filtrates were diluted with the same volume of ethanol. Carboxylic acids were pre-labelled with 2-nitrophenylhydrazine using the Short- and Long-Chain Fatty Acid Analysis Kit (YMC, Co. Ltd, Kyoto, Japan). The SCFA derivatives were subsequently extracted by n-hexane and diethyl ether and finally evaporated to a dry state. The residue was dissolved in methanol and filtered through a 0.45-µm membrane filter. A portion (10 µl) of filtrate was injected into an HPLC system with YMC-Pack FA column (250 × 6.0 mm; YMC Co., Ltd.). We applied the isocratic elution mode with the acetonitrile/methanol/water mobile phase (30:16:54, v/v) at 50°C. Six SCFAs (acetic, propionic, butyric, isobutyric, valeric and isovaleric acids) were measured for absorbance at 400 nm. The sum of individual SCFA concentrations was regarded as total SCFA.

Genetic analysis

Approximately one week after collecting the samples, we centrifuged the sample tubes at 14000 rpm for 10 min and discarded the supernatant (RNAlater solution). This was carried at Primate Research Institute, Kyoto University, Japan. The pelleted samples were then frozen at -80°C until extraction, except at the time of export to Switzerland on September 29 (31 hours, temperature <= 4°C at all times). Further analysis was conducted at the Department of Evolutionary Biology and Environmental Studies, University of Zurich, and the Functional Genomics Center Zurich. We added four zirconia beads (3 mm in diameter), 0.1 mg zirconia/silica beads (0.1 mm in diameter), and 500 µL of Inhibit Ex buffer of QIAamp Fast DNA Stool Mini Kit ® QIAGEN into the tubes and crushed the sample substrate with a bead crusher at 1800 rpm for 5 min. DNA was extracted by QIAamp Fast DNA Stool Mini Kit following the manufacturer's protocol. We quantified the DNA concentration with Qubit dsDNA HS Assay Kit and a Qubit fluorometer ®Thermo Fisher Scientific.

We conducted meta-16S analysis for both feces and SAF samples. We amplified the V3-V4 region of the 16S rRNA gene with the following primer set: S-D-Bact-0341-b-S-17 (forward) CCT ACG GGN GGC WGC AG and S-D-Bact-0785-a-A-21 (reverse) GAC TAC HVG GGT ATC TAA TCC [58]. We chose this region because it has already been used for a previous study of Japanese macaques and it can represent the composition of gut microbe community as well as other regions, such as V1-V2 [56]. We purified the PCR amplicons using Agencourt AMPure XP beads ®Beckman Coulter, Inc. and then performed a second PCR (using the Illumina Nextera XT Index Kit) to attach

specific dual indices and sequencing adapters to each amplicon. DNA concentration of the 2<sup>nd</sup> PCR products were quantified and pooled so that the molarities of all samples were equalized. We evaluated the fragment size distribution with TapeStation ®Agilent Technologies, Inc. After Phi X spike-in, the library was sequenced on the Illumina Miseq platform (2 x 300 bp). Further details of the protocol are described in Hayakawa et al. [56].

We conducted the shotgun metagenomics analysis for only feces samples. We fragmented the DNA with Covaris E220 ®M&S Instruments, Inc., following the manufacturer's recommended setting to make the average DNA size 200 bp (http://covarisinc.com/wp-content/uploads/pn\_010308.pdf). After confirming the fragment size by TapeStation, we prepared a library using Ultra™ II DNA Library Prep for Illumina ®New England Biolabs Inc. and sequenced it with the Illumina Hiseq 4000 platform (2 x 150 bp).

Data analysis

The difference in gas and SCFA production between the highland and lowland were tested by t-test using R 3.2.2.

For the 16S rRNA gene analysis, demultiplexing yielded 7,424,940 paired-end reads for downstream analysis (median/minimum per sample: 244,875/78,467). Reads were denoised with dada2 (version 1.12.1, [59]) using read truncation lengths of '280, 250', maximum expected errors of 8, pooling option 'pseudo,' maximum allowed mismatches when merging pairs of 3, and default values for all other options. Denoising resulted in 25,518 Amplicon Sequencing Variants (ASVs), which were subsequently aligned using INFERNAL (version 1.1.2, [60]) with the microbial secondary structure model

SSU-ALIGN. Based on this alignment, ASVs were further clustered into 2,541 *de novo* OTUs (97% sequence identity) using HPC-CLUST (version 1.2.1, [61]) with the average linkage option. Taxonomic classification was performed by mapping all ASVs with MAPseq (version 1.2.1, [62]) against its default reference database (MAPref 2.2b, see [63] for details on how it was generated). ASV-specific classifications were then summarized into consensus classifications per OTU by retaining only classifications with >90% assigned representatives (MAPseq confidence cutoff >= 0.5).

For phylogenetic tree construction, representative ASVs with the highest abundance were chosen for each OTU. Representatives were aligned using INFERNAL (see above), and the resulting alignment was subsequently used to construct a phylogenetic tree with FastTree (version 2.1.9, [64]) using the GTR substitution model and otherwise default options. Alpha- and Beta-diversity indices were computed using the python package scikit-bio (version 0.5.1, http://scikit-bio.org/), and standard statistical tests (Student's t-test for independent samples, Mann-Whitney U test) were performed with the python package scipy (version 0.19.1; https://www.scipy.org/). Differential abundance analysis on all OTUs and taxa found in at least five samples was conducted using edgeR (version 3.24.3, [65]) with robust dispersion (function estimate GLMRobustDisp) and normalization factor option TMM.

For the shotgun metagenomics analysis, de-multiplexing yielded 395,051,334 paired-end reads for downstream analysis. Read pairs were joined and filtered using mothur (version 1.38.1, [66]) using the "make.contigs" and "screen.seqs" methods (the latter with options maxambig 10, maxhomop 10, maxlength 480), which resulted in 373,262,340 filtered reads (5.5% removed).

To remove putative eukaryotic sequences, all filtered reads were mapped against KEGG (release 59, [67]) with the DIAMOND tool (version 0.8.38, [68], options "sensitive" and "-b 20") and all reads with a eukaryotic best hit were discarded (16,091,001, or 4.3%).

Based on all remaining reads, gene and pathway abundances were generated with HUMAnN2 (version 0.11.1, [69]) using the recommended UniRef90 database [70] for gene definitions and the MetaCyc database [71] for pathway definitions (both databases downloaded in February 2018), as well as relative abundance normalization (option "relab"). Level 4 EC identifiers were assigned based on HUMAnN2 utility mapping files. Standard statistical tests were performed using the python package scipy (see above).

Compliance with Ethical Standards

During the fieldwork, we adhered to the "Guideline for field research of non-human primates" of the Primate Research Institute, Kyoto University.

Furthermore, our procedure complied with ARRIVE guidelines for the use of animals in research (http://www.nc3rs.org.uk/ARRIVE), as well as the legal requirements of Japan. No prior consent from the Japanese government is required to export biological samples from Japan in the context of Convention on Biological Diversity (http://www.env.go.jp/en/nature/biodiv/abs/index.html).

Results

*In vitro* fermentation assay

We found the overall fermentation activity to be higher for fecal samples from the highland compared to the lowland, as evident from both significantly higher gas

production (6 h, 12 h, 18 h, and 24 h; Fig. 2a) and significantly lower pH (Fig. 2b). There was no significant difference in total SCFA production between the highland and lowland (Fig. 2c). Among the four SCFAs (acetic acid, propionic acid, butyric+isobutyric acids, and valeric+iso valeric acids), only the production of butyric acid (including isobutyric acid) was significantly higher for highland samples compared to lowland (Fig. 3). Prior to fermentation (time point 0 h), we found no significant difference in total SCFA concentration or for any of the four SCFA classes.

Comparisons of community structure of the fecal microbiota

We obtained 7,424,940 reads (median/minimum per sample: 244,875/78,467)

which were successfully demultiplexed, filtered and *de novo* clustered into 2541 operational taxonomic units (OTUs) using a 97% sequence identity cutoff (see Methods). Out of these OTUs, 1311 (51.6%) were classifiable at the phylum level or deeper. A summary of the phylogenetic assignment of the OTUs in each sample is shown in Supplemental Material 3.

The differences in relative abundance of major taxa (>1% at the phylum, class, order, family and genus levels) were all insignificant, except for significant enrichment of Anaeroplasmataceae in the highland (Supplemental Material 3, 4). Differential abundance analysis revealed 130 OTUs that were significantly enriched in highland (54) or lowland (76) samples. Enriched bacterial OTUs in the highlands were 12 OTUs of phylum Firmicutes, class Clostridia, order Clostridiales, one OUT of *Bacteroides uniformis* in the phylum Bacteroidetes, family Bacteroidaceae and the remaining 39 OTUs could not be mapped to any taxa. Enriched OTUs in the lowland included 16 OTUs of Bacteroidetes (all were

412 class Bacteroidia, order Bacteroidales), eight OTUs of Firmicutes (order 413 Clostridia and Negativicutes), two OTU of Proteobacteria, 23 OTUs of 414 Proteobacteria (all were *Treponema berlinense*) and 27 unmapped OTUs. 415 Average alpha diversity did not differ between the lowland and highland 416 as differences in observed OTUs: Chao1, Shannon and Faith's Phylogenetic 417 Diversity indices were all insignificant (Supplemental Material 1). 418 Community structure clearly differed between the highland and lowland, 419 based on pairwise Bray-Curtis dissimilarity (PERMANOVA, P = 0.001). In 420 addition to clustering separately from lowland samples, highland samples 421 furthermore showed increased variability and sub-structure (Fig. 4). This 422 sub-structure could not be explained by longitudinal differences, since eastern 423 and western samples did not cluster separately. 424 425 Comparisons of community structure between the feces and suspension after 426 fermentation (SAF) 427 Community structure of the SAF was significantly different from the 428 corresponding fecal samples (Fig. 4, PERMANOVA, highland: pseudo-F=1.86, 429 P=0.022; lowland: pseudo-F=3.06, P=0.001). Judging from the F and P values, 430 the difference in community structure between SAF and feces in the lowland was 431 larger than that in the highland. 432 The number of taxa showing significant changes in abundance 433 between SAF and feces was larger in the lowland (three phyla, four classes, six 434 orders, eight families, two genera and 104 OTUs) than in the highland (one 435 phylum, no class, one order, two families, one genus and 47 OTUs) (Table 1). 436 Among the major taxa (>1% of relative abundance in feces or SAF), significantly

more enrichment in SAF than in feces was detected for Proteobacteria (highland and lowland) and Spirochaetes at the phylum level and Streptococcaceae (highland and lowland), Succinivibrionaceae (lowland), and Pasteurellaceae (lowland) at the family level and *Streptococcus* (highland and lowland) at the genus level.

None of the alpha diversity indices differed significantly between feces and SAF in either the highland or the lowland (Supplemental Material 1).

Metagenomic analysis of the fecal microbiota

After having assessed the community composition, we next focused on systematic and specific functional (gene and pathway) differences between highland and lowland microbiota. To this end, we conducted whole-genome shotgun sequencing on all fecal samples, which yielded 373,262,340 reads, or 14,356,243 reads/sample, after de-multiplexing and filtering. PERMANOVA analysis (based on pairwise Bray-Curtis dissimilarity) showed a statistically significant separation between lowland and highland samples in terms of both gene abundance (P = 0.001; Fig. 5a) and pathway abundance (P = 0.034; Fig. 5b). In contrast to abundance, pathway coverage showed no significant lowland-highland separation (P = 0.11; Fig. 5c).

Among 37 selected genes involved in the metabolism of polysaccharides and the synthesis of SCFAs from pyruvate, the abundance was not significantly different for any of the genes.

When mapping the presence and abs243ence of the selected genes on polysaccharide metabolism and SCFA synthesis pathways, most genes were uniformly present or uniformly absent in both the lowland and highland samples

(Supplemental Material 2). Regarding polysaccharide metabolism, most gut microbiota possessed genes to catalyze cellulose, xylan, mannan, and pectin degradation, all of which are lacking in the genome of rhesus macaques (the most closely related species of Japanese macaques with a published genome). Pathways for the synthesis of acetate, butyrate, and propionate from pyruvate were all inter-connected for most fecal metagenomes, both in the lowland and highland, and also within the macaque reference genome.

Out of 263 tested MetaCyc [71] pathways (present in > 10 samples), two showed a significant difference in abundance between highland and lowland samples: GLYCOGENSYNTH-PWY (glycogen biosynthesis I, from ADP-D-Glucose); Mann-Whitney U test, P = 0.041, Benjamini-Hochberg adjusted) and GALACTUROCAT-PWY (D-galacturonate degradation I; Mann-Whitney U test, P = 0.044, Benjamini-Hochberg adjusted), both of which were more abundant in lowland.

Discussion

Difference in fermentation ability between highland and lowland

The *in vitro* fermentation assay clearly indicated that the fermentation ability of leaves was higher for highland gut microbiota compared to lowland communities. In the highland, where the macaque diet is leaf-based, the corresponding communities produced significantly more gas and induced a significantly larger decrease in pH during fermentation. While they also showed a trend toward increased SCFA production, this difference was not significant. We note, however, that this may be caused by power issues due to decreased sample size compared to the gas and pH measurements (nine samples were not

included, see Methods). SCFAs are utilized as an energy source by the host, and they constitutes a considerable portion in both human and non-human primates' energy intake [18, 19]. Taken together, our results indicate that the higher leaf-fermentation potential of highland gut communities may facilitate digestion of the leaf-based diet of highland macaques, compared to the lowland animals. While more research is necessary, this finding highlights the potential importance of the gut microbiome for generalist hosts (such as the macaques studied here) to flexibly respond to and benefit from changing food conditions. Interference experiments on humans show that dietary changes can modify the gut microbiome within only a few days (2-5) [72], so the gut microbiota of macaques in the highland and lowland, living separately for years (in the case of philopatric females) or months (in the case of immigrant males), likely have sufficient transition time to respond to different dietary regimes.

The assay also suggested that the fermentation system was different between the two areas. When investigating individual classes of SCFAs, we found butyric acid production to be significantly increased in highland compared to lowland samples. Many bacteria are capable of acetic acid production, but propionic or butyric acid producers are generally less common [34]. Furthermore, biosynthesis pathways for butyric acid are highly diverse and can often vary even within a single bacterial family [34]. Some butyrate producers can produce butyrate with the aid of other bacteria. For example, lactate is produced by other species, and the resultant lactate is converted to butyrate by lactate users, such as *Megasphaera* [73]. Increased butyric acid production has been reported in many different contexts: for example, butyric acid in feces has been reported to be higher when energy intake decreased in howler monkeys [31], while butyric

acid production increased with higher fruit consumption in gorillas [74]. For human hosts, the situation is generally mixed, since some interference experiments in which additional fiber was added to the normal diet led to increased fecal butyrate concentration, while other studies did not report such increases [75]. Our finding of increased butyric acid production in highland microbiota (exposed to leaf-based diets) contributes to this growing body of research and, while the overall picture is still complex, provides additional evidence for a link between high-fiber diets and the production of this SCFA. Meta-16S analysis: Gut microbiota community structure Gut community structure was clearly clustered between the highland and lowland populations in Yakushima. A previous study using the meta-16S analysis of wild and captive Japanese macaques included samples collected in the highland and lowland Yakushima (N=18), which also indicated clear differentiation of gut microbe community structure between the two areas [44] (Supplemental Materials 5). We did not directly compare those results with the current study because the methods of that previous study were not the same as the method used in the current work, nevertheless that study provided further confirmation of the validity of our findings. While we observed higher OTU profile variation and considerable sub-structure within highland samples compared to lowland ones, this sub-clustering did not correspond to longitudinal differences in sampling locations (i.e. east vs. west). This is interesting because western highland macaques live in the immediate geographical vicinity of the lowland population (in contrast to the eastern highland population), but this co-locality is

not reflected by a higher similarity in the gut microbe community. It thus seems

that habitat similarity, rather than physical contact between hosts (typically via male immigration and emigration) [76], is responsible for shaping the gut communities. Unmeasured factors related to group identity may provide an alternative explanation for the sub-structure within highland samples, but more data would be needed for definite conclusions.

Comparisons between feces and suspension after fermentation (SAF) indicated that the community structure of the microbiota was significantly altered during fermentation than it used to be in the gut. This alteration seems to be larger for lowland than highland, evidenced by the F and P statistics and the larger number of taxa showing changes in abundance. This suggests that the difference between the experimental and original conditions in the gut was larger for lowland than for highland microbiota, which is consistent with the fruit-based diet in the lowland.

The comparisons of differential abundance between the feces and SAF may give us a clue to the bacterial taxa that are responsible for the fermentation activity. For example, Succinivibrionaceae (phylum Proteobacteria, class Gammaproteobacteria, order Aeromonadales) increased during fermentation. This family is reported to increase in the feces of wild Tibetan macaques during winter, when they eat more leaves [29]. Interestingly, however, in the rumen of cows, this family increased when the animals are supplied with low-fiber diet [77]. Another example is *Streptococcus* (phylum Firmicutes, class Bacilli, order Lactobacillales, family Streptococcaceae). This genus includes the species with tanning-binding ability [20, 21], which may be useful for digesting leaves. Feces of feral pigs with high feed efficiency, and thus with a higher ability to degrade cellulose, contain more *Streptococcus* [78]. These studies are consistent with

our results that this genus increased during the assay using mature leaves as a substrate. However, in wild howler monkeys, this genus increased when they ate low-fiber foods (fruits) [31]. The Succinivibrionaceae and *Streptococcus* examples show that the same taxa may exhibit a different function in fermentation in different hosts. We note, however, that even one species of microorganisms has a wide variety of genes and thus metabolic potential [79] and, therefore, we can expect the deviations at the higher taxonomic levels. Furthermore, it has been shown for different environments that stable community function can be retained even under high species turnover [80, 81]. For the same trait—especially if it features many species and pathways, such as in fiber digestion—taxonomic composition may therefore differ widely. Our results further underscore this notion and caution against generalized assumptions on community function that are based solely on taxonomy.

In contrast to a recent study on fecal microbiota of the same host species [56], a large fraction of OTUs (48.4%) could not be taxonomically classified even at the phylum level in our analysis. This difference is due to the more precise mapping approach we used here (MAPseq; [62]), which assigns low confidence to a read if multiple taxa have similar alignment scores and can thus not be confidently distinguished. In various benchmarks, this approach was shown to yield better classifications than the commonly used less conservative alternatives [62, 82]. The high fraction of largely unclassified OTUs may be an indication that much is still to be learned about the macaque gut microbiome.

Metagenomic analysis: Difference with respect to the genes and pathway composition

Metagenomic analysis indicated that highland and lowland populations also differed on the level of genes and pathways. This shows that the function of the gut microbe varies between the two areas, in which macaques experience different food and thermal conditions [46, 83].

For example, we found two pathways that differed in abundance between highland and lowland samples, which may be related to the lifestyle of the host animals. For example, the glycogen biosynthesis I pathway was more abundant in the lowland samples. Glycogen is synthesized to store excess glucose temporarily in the liver [84]. The main food in the sampled season in the lowland of Yakushima is the sapfruit of Myrica rubra [85], which is considered one of the most sugar-rich fruits available in Yakushima [86]. Therefore, lowland macaques may experience situations of having excess glucose more often than leaf-eating highland macaques. Genes in this pathway could thus be beneficial for storing excess glucose and using it as an energy source in the subsequent food-scarce season. In contrast, in the highland, saving the function of the pathway may be advantageous when the macagues do not eat fruits. The D-galacturonate degradation I pathway was also enriched in the lowland; D-galacturonate is an oxidized form of galactose, and it is included in many polysaccharides in plants, including pectin [87]. This pathway may also be related to the fruit-dominated diet in the lowland, but this remains unknown without detailed knowledge of the metabolomics profile of their foods.

We did not find a genetic difference which can directly account for the observed differences in fermentation ability between highland and lowland.

Among the 37 genes encoding enzymes that catalyze the majority of upstream and downstream reactions in the degradation of polysaccharides to SCFAs, we

found no difference in enrichment patterns for any of the genes. It was evident that the gut microbiota in both regions possess genes necessary for the synthesis of SCFAs from polysaccharides but are lacking in the host genome (assuming it is the same as that of rhesus macaques). Although not as important as in the highland, leaves are also one of the main foods in the lowland [50], and all of these genes may be necessary for survival in both areas.

Implications of the flexibility in digestive ability

In this study, we demonstrated that the gut microbiome of macaques is shaped according to habitat and diet, in terms of both community structure (taxa, OTUs) and the function (genes, pathways). Furthermore, we showed that these differences affect the ability to digest leaves and thus may play an important adaptive role in this generalist host. Since similar alterations in the gut microbial community composition in response to dietary changes are a well-known fact in many hosts [22], we predict similar microbiome-mediated increases in digestive ability for commonly consumed foods in many other generalist animals.

We can point out a number of limitations in the interpretations of the current study. The inoculum of this assay is feces, not gut contents. Even though fecal samples are usually used as a representative of 'gut' (colon) microbiota, these microbiota are subject to changes immediately after defecation due to biotic and abiotic factors [88]. We found no difference in the fecal SCFA, or 0 h concentrations between the highland and lowland. It is possible that this was simply due to the smaller sample size than gas production reduced by mistake, but it is also possible that the difference was a real one. Fecal SCFA concentration is determined not only by the microbiota but also by the digesta,

which are derived from many different kinds of foods in the case of wild animals. Some bacteria in feces in the lowland may have worked to produce as much SCFAs *in vivo* as in the highland in the presence of natural foods, but not when supplied with only leaves of *E. japonica*. Therefore, different substrates should be tested in the future to confirm our conclusion.

The above limitations of the current in vitro fermentation assay suggest that further improvement of this method is possible as a way to reveal the fermentation ability of the gut microbe. In this study, we examined only one type of substrate, but it is possible to divide the fecal samples into multiple portions and use these as an inoculum for different substrate types. Similarly, we investigated leaf-fermentation ability only for one plant species eaten frequently in the highland but only rarely in the lowland; consequently, it would also be interesting to test the fermentation of substrates commonly eaten in the lowland, since these may be processed more efficiently by microbial communities from lowland hosts. In our assay, the fermentation time was set to 24 h, which approximates the typical retention time in the hindgut of Japanese macaques (total gut retention time can be up to 35 h when feeding on high-fiber foods; [89]). However, retention time can vary based on different factors, including the body size of the animal, and this should be taken into consideration in future studies. Furthermore, our time-series data on gas production suggest that the fermentation process is time-dependent, so it may be possible to mimic the in vivo digestion process much better via a more dynamic and flexible experimental setup, including substrate preparation and the duration of fermentation. In future studies, it will also be necessary to evaluate the relative contribution of the fermentation by the gut microbiome compared to the enzymatic digestion by the

host. This is necessary to better understand how gut microbial shifts can affect the digestion and survival of the host. Another interesting avenue of study would be to complement the metagenomics data used here with approaches based on metabolomics [36, 74] and metatranscriptomics [16, 90] approaches, which could provide deeper insights into the molecular basis and mechanisms affecting the fermentation potential. It would also be interesting to isolate bacteria species from the feces and to explore its function, for example, by sequencing the whole genome. We have already isolated and sequenced the genome of *Sarcina ventriculi* from the feces of Japanese macaques in the highland [91]. The genome includes potentially important genes for the digestion of leaves, such as cyanate metabolism. Interestingly, this bacteria cannot be isolated from feces collected in the lowland. Using combinations of these multi-level approaches would clarify the mechanism that produces different fermentation abilities among the host animals living in different environments.

In conclusion, we demonstrated that gut microbe community structure differed considerably between the two investigated habitats, which may in part be explained by habitat-specific diets. In support of this, via an *in vitro* fermentation assay, we showed that gut microbiota of the more leaf-eating highland Japanese macaques have a higher fermentation ability for leaves than those of the more fruit-eating lowland animals. Taken together, our results indicate that gut microbiota may help generalist hosts to improve their digestive ability in response to the variations on food availability.
