Abstract

Aims We sought to investigate the time course of cardiac disorders after catheter ablation for atrial fibrillation (AF) in patients with coexisting heart failure (HF) during long-term follow-up.

Methods and results We analysed consecutive 280 patients undergoing first-time catheter ablation for AF who had coexisting HF, which was defined as prior HF hospitalization, estimated right ventricular systolic pressure ≥ 45 mmHg, or B-type natriuretic peptide (BNP) ≥ 200 pg/dL before the procedure. The primary endpoints were improvements in left ventricular ejection fraction (LVEF), E/e', BNP, left atrial dimension (LAD), and mitral regurgitation (MR) at 1 year. The secondary endpoints were serial changes of LVEF, E/e', BNP, LAD, and MR at 6 months, 1 year, and 5 years and cumulative incidence of HF hospitalization. During the mean follow-up of 5.1 ± 3.0 years, 70.7% of patients were free from recurrent AF. Among patients with LVEF < 50%, E/e' ≥ 15, BNP ≥ 200 pg/dL, LAD ≥ 40 mm, and moderate-to-severe MR, changes in those parameters from baseline to 1 year were $34.5 \pm 9.9\%$ to $43.2 \pm 14.4\%$ ($P < 0.001$), 19.7 ± 3.9 to 12.5 ± 6.6 ($P < 0.001$), 290 to 85 pg/dL ($P < 0.001$), and 100% to 37.8% ($P < 0.001$), respectively. The improvements in the cardiac disorders were maintained up to 5 years except for E/e'. In patients with LVEF < 40%, significant delayed improvement of LVEF beyond 1 year was observed (ΔLVEF = 10.5 ± 18.5, $P = 0.001$), but not in patients with LVEF of 40–49%. The cumulative incidence of HF hospitalization was 12.6% at 5 years. Baseline diastolic dysfunction was the only independent predictor for subsequent HF hospitalization.

Conclusions In patients undergoing AF ablation with coexisting HF, all cardiac disorders significantly improved after the procedure, which was mostly maintained during 5 year follow-up.

Introduction

Both atrial fibrillation (AF) and heart failure (HF) are common disease increasing with age and each disease predisposing to the other.[1] Atrial kick during a diastolic phase and atrioventricular synchronization disappear during AF rhythm. In addition, high-rate ventricular contraction induces systolic and diastolic dysfunction. Furthermore, high-rate atrial contraction leads to left atrial (LA) dilation, which causes secondary mitral regurgitation (MR). Conversely, HF also increases the incidence of AF, especially at the time of acute exacerbation and dehydration. Thus, AF begets HF and vice versa, leading to increased mortality and morbidities.[1–3]

Catheter ablation for AF has become increasingly popular as non-pharmacological rhythm control therapy.[4,5] In AF patients with coexisting HF and systolic dysfunction, several studies have reported the superiority of catheter ablation to conventional therapy in improvement of systolic

dysfunction.[6–9] Recently, a randomized controlled trial in AF patients with coexisting HF (CASTLE-AF study) firstly demonstrated significantly lower rate of death or worsening HF and higher rate of improvement in systolic dysfunction after catheter ablation for AF as compared with medical therapy.[10] However, long-term change in cardiac disorders after catheter ablation for AF in patients with coexisting HF has not been fully evaluated. In addition, predictors of the improvement in cardiac function have been rarely evaluated. Therefore, the recommendation level of catheter ablation for AF in HF patients is still Class IIb even in recent guidelines.[4,5] The aim of the current study is to investigate long-term impact of catheter ablation for AF on cardiac disorders in patients with coexisting HF.

Methods

Study population

Among 1206 consecutive patients undergoing radiofrequency catheter ablation for AF in Kyoto University Hospital between February 2004 and March 2015, 280 patients with coexisting HF were included in the current study. HF was defined as prior HF hospitalization, lung congestion on echocardiography (estimated right ventricular systolic pressure $\geq$45 mmHg), or biological cardiac overload [B-type natriuretic peptide (BNP) $\geq$200 pg/dL] at the time of the procedure.[11] Written informed consent was obtained from all patients. A 12-lead electrocardiogram was routinely measured at each clinical visit, and 24 h Holter monitoring was recommended at 3, 6, and 12 months and yearly thereafter. Follow-up information was obtained by review of hospital chart and/or contact with the patient, relatives, and/or referring physicians. The study protocol was approved by the institutional review board of Kyoto University Hospital.

Ablation procedure and post-procedural management

Extensive encircling pulmonary vein isolation and tricuspid valve isthmus ablation were routinely performed. Superior vena cava isolation, LA linear ablations, and additional complex fractionated atrial electrogram ablation were performed if necessary. The detail of ablation procedure was described in our previous report.[12] After the first procedure, oral anticoagulant was continued for at least 3 months. Thereafter, discontinuation of oral anticoagulant in patients without arrhythmia recurrence was left to the discretion of the attending physician. Antiarrhythmic drugs were discontinued before the ablation procedure and were restarted only when recurrent atrial tachyarrhythmias were detected. The second procedure was recommended to the patients with recurrent atrial tachyarrhythmias after the blanking period of 3 months.

Definitions and outcome measures

Atrial fibrillation was classified into paroxysmal (lasting <7 days) and persistent (lasting $\geq$7 days) AF. 'C' as a component of CHADS$_2$ and CHA$_2$DS$_2$-VASC scores included hospitalization for exacerbation of HF within 100 days before the index ablation procedure and/or left ventricular (LV) ejection fraction (LVEF) of <40%. Other components of the scores were described elsewhere.[13,14] Stroke was defined as neurological deficit requiring hospitalization with symptoms lasting for >24 h. Recurrent AF after procedure was defined as documented AF and/or atrial tachycardia lasting for >30 s or those requiring repeat ablation procedures with a blanking period of 90 days after procedure.[15] Maintained sinus rhythm was defined as free from recurrent AF without antiarrhythmic drugs.

Systolic dysfunction was defined as LVEF < 50% and was further subclassified into two groups [HF with reduced LVEF (HFrEF): LVEF < 40%; HF with mid-range LVEF (HFmrEF): LVEF 40–49%].[16] HF with LVEF $\geq$ 50% was considered as HF with preserved LVEF (HFpEF). Diastolic dysfunction, LA dilation, and significant MR were defined as E/e' $\geq$ 15, LA dimension (LAD) $\geq$40 mm, and moderate-to-severe MR, respectively.

The primary outcome measures were improvements of cardiac functions at 1 year, including LV systolic function (ΔLVEF $\geq$ 10% or normalization of LVEF to $\geq$50%), LV diastolic function (normalization of E/e' to <15), BNP level (reduction to half of the baseline level or normalization to <200 pg/dL), LAD (ΔLAD $\geq$ 10% or normalization to <40 mm), and MR (reduction to none or mild grade).[9] The secondary outcome measures were serial changes of all those parameters at 6 months, 1 year, and 5 years, as well as the cumulative incidence rates of all-cause death and HF hospitalization during follow-up.

Statistical analysis

Categorical variables were presented as number and percentage and were compared with χ^2 test or Fisher's exact test. Continuous variables were presented as mean with standard deviation or median with inter-quartile range and were compared using Student's t-test or the Wilcoxon rank-sum test based on their distributions. The cumulative incidence and the event-free rates were estimated by the Kaplan–Meier method, and the differences were assessed by the log-rank test.

Logistic regression or Cox proportional hazard analysis with clinically relevant variables was conducted to identify independent risk factors for recurrent atrial tachyarrhythmia,

the improvement of cardiac disorders, all-cause death, and HF hospitalization after the ablation procedure. Because of the limited number of events, only variables with $P < 0.10$ or <0.30 on univariate analysis were included in the multivariable model. Statistical analyses were performed using JMP Pro 14 (SAS Institute Inc., Cary, NC) software. All analyses were two-tailed, and P value of <0.05 was considered statistically significant.

Results

Baseline characteristics

The baseline characteristics of the 280 study patients were summarized in *Table 1*. Mean age was 66.8 ± 8.5 years, and 34.6% were female. Mean CHADS$_2$ and CHA$_2$DS$_2$-VASc scores were 1.6 ± 1.1 and 2.7 ± 1.5, respectively. Majority of patients had a previous history of hospitalization for HF exacerbation before the ablation procedure. Median BNP level was 232 (132–349) pg/dL, and 64.1% of patients had BNP level of ≥ 200 pg/dL. Regarding baseline echocardiographic parameters before the index procedure, LV diastolic dimension (LVDd), LVEF, LAD, and E/e′ were 58.0 ± 8.1 mm, $53.3 \pm 17.7\%$, 44.3 ± 6.5 mm, and 13.4 ± 6.2, respectively. The prevalence of baseline systolic dysfunction, diastolic dysfunction, LA dilation, and moderate-to-severe MR was 40.4%, 30.0%, 78.9%, and 19.3%, respectively. About half of patients received angiotensin-converting enzyme inhibitor or angiotensin receptor blocker, and beta-blockers. Most baseline characteristics were comparable between patients with and without diastolic dysfunction, except for higher age, higher CHADS$_2$ score, larger LAD, and higher prevalence of paroxysmal AF in patients with diastolic dysfunction (Supporting Information, *Table S1*).

Recurrent atrial fibrillation after ablation procedure

Mean follow-up duration was 5.1 ± 3.0 years. The event-free survival from recurrent atrial tachyarrhythmias after the first procedure was 42.1% at 5 years (Supporting Information, *Figure S1*). During follow-up period, the prevalence of multiple procedures was 42.2% (Supporting Information, *Figure S2*). The event-free survival from recurrent atrial tachyarrhythmias after multiple procedures was 91.3% at 6 months, 87.0% at 1 year, 77.0% at 3 years, and 70.7% at 5 years, respectively. In the multivariable analysis, the independent predictors for arrhythmia recurrence were LVDd ≥ 55 mm [hazard ratio (HR) 2.10, 95% confidence interval (CI) 1.19–3.55, $P = 0.01$] and LAD ≥ 40 mm (HR 2.50, 95% CI 1.25–5.72, $P = 0.008$) (Supporting Information, *Table S2*).

ACE-I, angiotensin-converting enzyme inhibitor; AF, atrial fibrillation; ARB, angiotensin receptor blocker; BNP, B-type natriuretic peptide; Ca, calcium; eGFR, estimated glomerular filtration rate; NYHA, New York Heart Association.
Categorical variables are presented as number (percentage). Continuous variables are presented as mean ± standard deviation or median and inter-quartile range.

Improvements in cardiac disorders at 1 year

The primary outcome measures of the current study were improvements in cardiac disorders at 1 year after ablation. Among patients with systolic dysfunction (LVEF < 50%), diastolic dysfunction (E/e′ $\geq$ 15), high BNP level (BNP $\geq$ 200 pg/dL), dilated LA (LAD $\geq$ 40 mm), and moderate-to-severe MR, changes in those parameters from baseline to 1 year were $34.5 \pm 9.9\%$ to $43.2 \pm 14.4\%$ ($P < 0.001$), 19.7 ± 3.9 to 12.5 ± 6.6 ($P < 0.001$), 290 to 85 pg/dL ($P < 0.001$), and 100% to 37.8% ($P < 0.001$), respectively (*Figure 1A*). The prevalence of significant improvements in those parameters at 1 year was 64.4%, 50.0%, 81.1%,

Figure 1 Improvements in cardiac disorders at 1 year after procedure. (A) Serial changes of cardiac parameters in patients with cardiac disorder. (B) The prevalence of significant improvements in cardiac disorders at 1 year. BNP, B-type natriuretic peptide; LAD, left atrial dimension; LVEF, left ventricular ejection fraction; MR, mitral regurgitation.
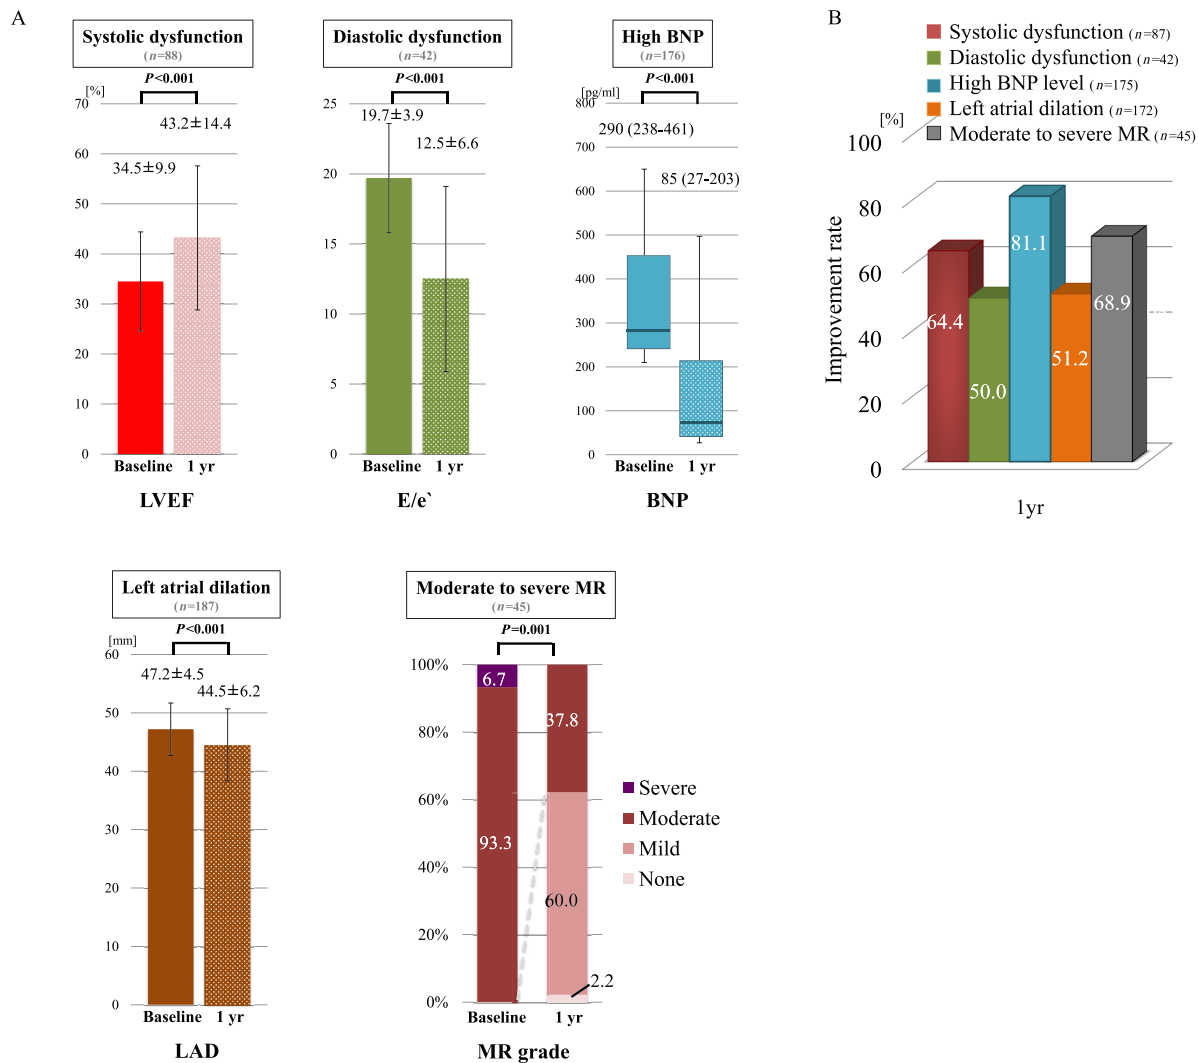

51.2%, and 68.9%, respectively (*Figure 1B*). In the multivariable analysis, LV dilation (LVDd ≥ 55 mm) was an independent negative predictor for the improvement of LVEF at 1 year (HR 0.18, 95% CI 0.05–0.59, P = 0.004). Other independent predictors of improved LVEF were persistent AF (HR 4.20, 95% CI 1.52–12.8, P = 0.005) and moderate-to-severe MR (HR 5.52, 95% CI 1.49–25.3, P = 0.009) (*Table 2A*). The independent negative predictors for reduction in BNP level were baseline dilated LV (HR 0.27, 95% CI 0.09–0.88, P = 0.03) and diastolic dysfunction (HR 0.33, 95% CI 0.12–0.88, P = 0.03) (*Table 2B*). The independent predictors for reverse remodelling of the LA were baseline moderate-to-severe MR and maintained sinus rhythm (*Table 2C*). There were no independent predictors for improvements in LV diastolic function and MR (Supporting Information, *Tables S3* and *S4*).

Time course of changes in cardiac disorders

The improvements in most cardiac disorders were maintained up to 5 years after ablation, although E/e' at 5 years was not significantly different from E/e' at baseline (P = 0.08) (*Figure 2*). In both HFmrEF and HFrEF patients, LVEF significantly increased at 6 months. Delayed improvement in LVEF beyond 1 year after procedure was observed in HFrEF patients (ΔLVEF = 10.5 ± 18.5, P = 0.001), but not in HFmrEF patients (ΔLVEF = 1.0 ± 8.9, P = 0.64) (Supporting Information, *Figure S3*). The prevalence of significant improvements in patients with systolic dysfunction, diastolic dysfunction, high BNP level, dilated LA, and moderate-to-severe MR at 5 years was 86.2%, 66.7%, 85.4%, 62.0%, and 73.7%, respectively (Supporting Information, *Figure S4*).

Impact of cardiac disorders and co-morbidities on clinical outcomes after atrial fibrillation ablation

The cumulative all-cause mortality was 2.1% at 1 year and 11.7% at 5 years (Supporting Information, *Figures S5* and *S6*). The cumulative incidence of HF hospitalization was 3.6% at 1 year and 12.6% at 5 years. Both risks were much higher in patients with baseline diastolic dysfunction than those without (40.4% vs. 4.0%, $P < 0.001$ for all-cause death, and 20.3% vs. 8.1%, $P = 0.03$, for HF hospitalization) (*Figure 3*), whereas there were modest or no significant differences between patients with and without other cardiac disorders (Supporting Information, *Figures S5* and *S6*). After adjustment of baseline differences by the multivariable Cox regression model, diastolic dysfunction remained independent risk factor for both all-cause death (HR 6.81, 95% CI 2.47–21.8, $P < 0.001$) and HF hospitalization (HR 2.95, 95% CI 1.03–8.46, $P = 0.04$) (*Table 3*).

Discussion

The main findings of the current study enrolling patients undergoing AF ablation who had coexisting HF were as follows: (i) all cardiac disorders including LV systolic and diastolic dysfunctions, high BNP level, dilated LA, and moderate-to-severe MR were significantly improved at 1 year after the procedure; (ii) most of those improvements were maintained up to 5 years after the procedure, except diastolic dysfunction; (iii) significant delayed improvement in LVEF beyond 1 year was observed in HFrEF patients with LVEF of <40%, but not in patients with HFmrEF patients with LVEF of 40–49%; (iv) normal LVDd, persistent AF, and moderate-to-severe MR were independent predictors for the improvement of LVEF; and (v) baseline diastolic dysfunction was an independent predictor for all-cause death and HF hospitalization.
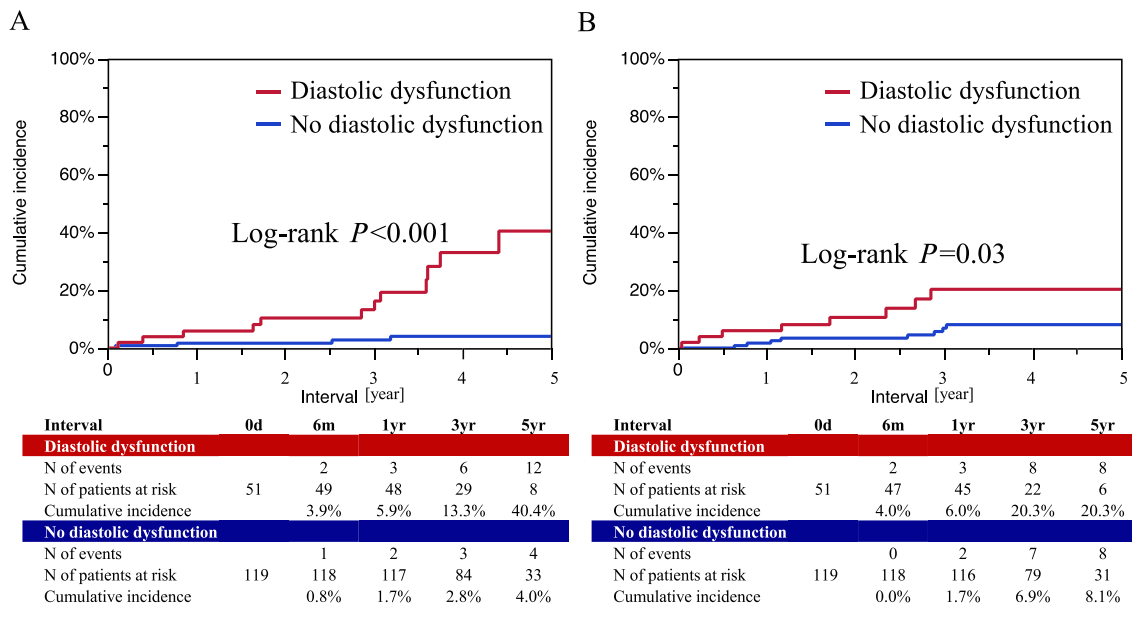

Figure 2 (A–E) Long-term time course of cardiac parameters in patients with cardiac disorder. BNP, B-type natriuretic peptide; LAD, left atrial dimension; LVEF, left ventricular ejection fraction; MR, mitral regurgitation.
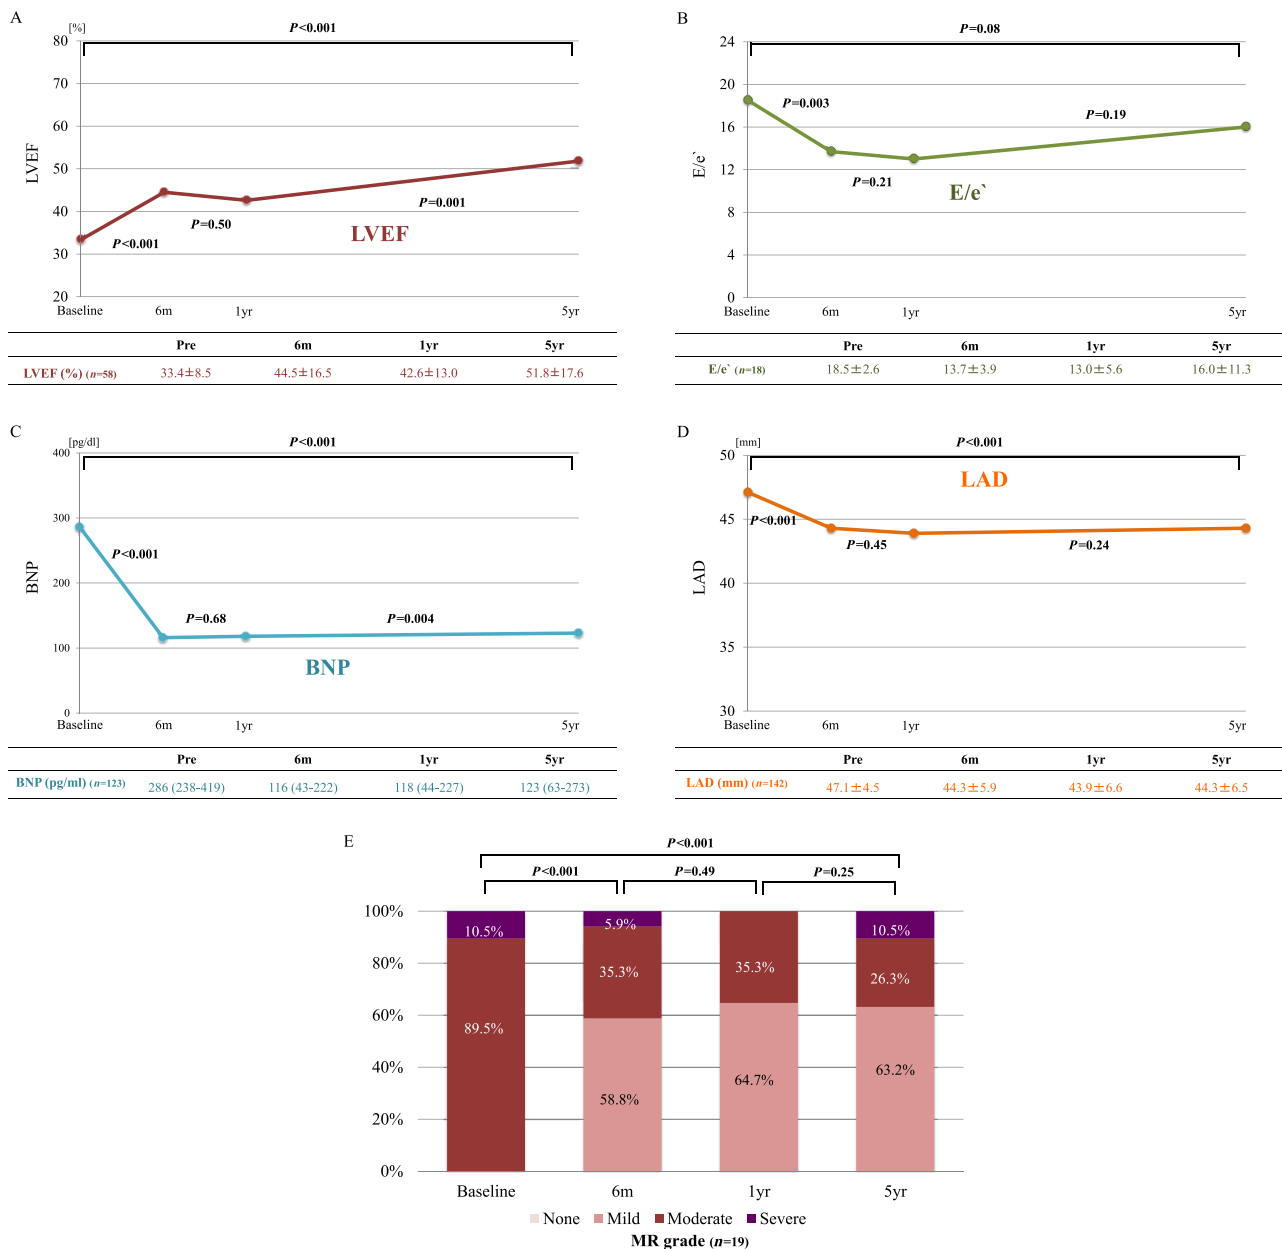

The development of AF has harmful effect on HF patients regardless of the presence of systolic dysfunction.[1,2] In 2004, two studies reported that restoration of sinus rhythm by catheter ablation for AF improved LVEF in HFrEF patients.[6,7] Thereafter, several randomized clinical studies demonstrated the superiority of AF ablation over medical therapy in HFrEF patients.[8–10] Recently reported CASTLE-AF trial investigated whether catheter ablation for AF decreases the risks for HF hospitalization and mortality as compared with medical therapy in HFrEF patients.[10] Catheter ablation was associated with significantly lower rates of all-cause death and HF hospitalization by reducing AF burden. However, there have been few data regarding the time course of improvement in LVEF as well as that in E/e, BNP, LAD, and MR during long-term follow-up. In the current study, all those parameters of cardiac function significantly improved at 1 year and were maintained throughout the follow-up period of 5 years except for diastolic function.

In the current study, ΔLVEF at 5 years after ablation in patients with LVEF < 40% was 18.4%, which was much higher than ΔLVEF of 7.3% at 5 years in the CASTLE-AF study. This is mainly due to the difference in patient selection between the current study and CASTLE-AF trial. In the current study, the population was consecutive patients undergoing AF ablation who had coexisting HF, and AF was considered the main cause of reduced LVEF in majority of patients. On the other hand, in the CASTLE-AF trial, the study population consisted of patients with New York Heart Association (NYHA) Class

II–IV HF, LVEF ≤ 35%, and prior implantation of a cardioverter defibrillator or a cardiac resynchronization therapy defibrillator, suggesting that underlying cardiomyopathy rather than AF was the main cause of reduced LVEF in most patients. Notably, in the current study, significant delayed improvement in LVEF was observed beyond 1 year after the ablation procedure. The delayed improvement was significant only in HFrEF patients with LVEF of <40%, but not in HFmrEF patients with LVEF of 40–49%. Normal LV size, persistent AF, and moderate-to-severe MR were the independent predictors for the improvement in LVEF at 1 year. Thus, patients with those baseline parameters are considered good candidates for AF ablation with coexisting HF.

Diastolic dysfunction is considered the most important cause of HF in HFpEF patients,[17,18] and no medical treatment has been reported to improve their prognosis.[19,20] Regarding AF ablation for HFpEF patients, few studies focused on the improvement of diastolic dysfunction. Machino-Ohtsuka et al. reported that sinus rhythm restoration by AF ablation improved diastolic dysfunction in 74 patients with HFpEF during 34 month follow-up period.[21] In the current study, diastolic dysfunction significantly improved at 1 year after procedure in 50% of patients, and mean E/e′ decreased from 19.7 at baseline to 12.5 at 1 year ($P < 0.001$). However, E/e′ at 5 years was not significantly different from E/e′ at baseline, although delayed increase in E/e′ from 1 to 5 years was not significant. Given the fact that diastolic dysfunction was the strong independent predictor for both all-cause death and HF hospitalization in the current study, whether diastolic dysfunction is likely to relapse beyond 1 year after AF ablation should be evaluated in future larger studies.

B-type natriuretic peptide level markedly and promptly reduced after AF ablation, which was maintained throughout the follow-up period. Regarding negative remodelling of the LA, reduction of LAD was modest but significant, which was in accordance with previous studies,[22,23] and was maintained up to 5 years after the ablation procedure. Sinus rhythm maintenance was an independent predictor for negative remodelling of the LA.

The current study has several limitations. First, the current study was a retrospective observational study with inherent biases. Second, complete serial echocardiographic data up to 5 years after procedure were available only in relatively small number of patients, precluding us from drawing any definitive conclusions. Third, we had no control group of AF patients with coexisting HF not undergoing AF ablation and could not assess the relative utility of ablation on cardiac function and clinical outcomes. Fourth, we had no information regarding NYHA class during follow-up and could not assess the impact of AF ablation on NYHA class. Also, data regarding 6 min walk test and quality-of-life scores were not available. Finally, the multivariable analyses might have not adequately eliminated the influence of unmeasured confounders on determining the independent predictors of improvements in cardiac disorders and clinical outcomes.

In conclusion, among patients undergoing AF ablation who had coexisting HF, LV systolic and diastolic dysfunctions as well as high BNP level, dilated LA, and moderate-to-severe MR improved in majority of cases at 1 year, which was maintained up to 5 years after the procedure except for LV diastolic function. Significant delayed improvement in LVEF beyond 1 year after the procedure was observed in patients with reduced LVEF of <40%. Normal LV size, persistent AF, and moderate-to-severe MR were the independent predictors for improvement in LVEF. Therefore, patients with those baseline parameters are considered good candidates for AF ablation with coexisting HF. Although LV diastolic dysfunction was the strong independent predictor of all-cause death and HF hospitalization, the impact of AF ablation on long-term diastolic function should be evaluated in future larger studies.
