## ABSTRACT

The evolution of both the first- and second-order Raman spectra of carbonaceous material (CM) through successive contact and regional metamorphic events is explored in the western part of the Ryoke belt (Iwakuni-Yanai area, SW Japan). Thirty-two metasedimentary rock samples were collected along a N-S gradient locally affected by contact metamorphism *before* and *after* the main regional tectono-metamorphic event (DP1). First-order spectra document a decreasing peak area ratio R2 and an increasing temperature  $T_{CM}$  towards the south and the surrounding granitoids. Domains with intermediate (535–600 °C)  $T_{CM}$  values match the extent of the pre-DP1 contact aureole but also image a so far unclear post-DP1 aureole. The axial part of the belt, likely unaffected by granite intrusions, preserves southward increasing  $T_{CM}$  from 425 to 660 °C. Second-order spectra show a single S1 band that splits into two peaks (S1- and S1+) whose frequency difference  $\Delta S1$  increases stepwise towards the south. The spatial distribution of  $\Delta S1$  follows that of the E–W trending regional metamorphic zones. The splitting of S1 indicates a transition from two-dimensional to three-dimensional CM and occurs at ~500 °C, which seems to be common to all metamorphic belts worldwide. Despite regional metamorphism CM was able to record the post-DP1 contact overprint and there is no clear observation of delayed CM recrystallization, which likely depends on the crystallinity of the CM precursor. A discrepancy between first- and second-order Raman parameters suggests that they partly record the influence of different factors; R2 gives an account of thermal events, particularly those related to localized contact metamorphism, whereas  $\Delta S1$  potentially yields information on regional variations in heating duration and pressure. This demonstrates the potential of the full Raman spectrum of CM for deciphering the complex thermal history of orogenic systems.

## 1. Introduction

Organic matter, if not fully decomposed in a near-surface environment, is buried together with other mineral detritus and incorporated into sedimentary rocks. Due to subsequent diagenesis and metamorphism this carbonaceous material (CM) will structurally and compositionally change from a C ± H ± N ± O ± S-bearing organic compound to eventually pure graphite (e.g. Buseck and Beyssac, 2014).

The transformation of CM with metamorphic grade has been investigated by chemical and X-ray diffraction (XRD) analyses (e.g. French, 1964; Grew, 1974; Griffin, 1967; Itaya, 1981; Izawa, 1968; Landis, 1971; Tagiri, 1981; Wang, 1989), transmission electron microscopy (e.g. Bénny-Bassez and Rouzaud, 1985; Beyssac et al., 2002b; Buseck and Huang, 1985; Buseck et al., 1987) or Raman spectroscopy (e.g. Pasteris and Wopenka, 1991; Wopenka and Pasteris, 1993). The latter

method allows in situ analysis of CM and provides information on CM crystallinity by means of the first-order spectrum (e.g. Knight and White, 1989; Pimenta et al., 2007; Tuinstra and Koenig, 1970), but also on three-dimensional ordering of CM thanks to the second-order spectrum (e.g. Beyssac et al., 2019; Cançado et al., 2008; Lespade et al., 1984; Wilhelm et al., 1998). A major advance related to this technique was that systematic changes in the first-order Raman spectrum of natural samples could be correlated with independent temperature estimates to derive a geothermometer (Beyssac et al., 2002a).

Thermometry based on Raman spectroscopy of carbonaceous material (RSCM) was calibrated using material from various geological settings. For the 330–650 °C temperature range, Beyssac et al. (2002a) used samples from worldwide belts affected by regional metamorphism while Aoya et al. (2010) relied on samples from contact metamorphic aureoles in Japan. The applicability of RSCM thermometry was extended to lower temperature (150–400 °C) by Rahl et al. (2005) with very-low-grade forearc metasediments, by Lahfid et al. (2010) with flysch sediments collected along a low-grade gradient, and by Kouketsu et al. (2014a)

with regionally metamorphosed low-grade metasedimentary rocks. The important aspect of all these calibrations is that they rely on originally non- to weakly-metamorphosed samples that were affected by a single heating event.

Orogenic systems are, however, commonly characterized by successive and partly overprinting thermal events (e.g. Brown, 1993). This led Delchini et al. (2016) to address the validity of RSCM thermometry in a complex setting, namely regionally metamorphosed Variscan metasediments overprinted by contact metamorphism. They concluded that RSCM analyses of samples previously affected by greenschist to amphibolite facies regional metamorphism can still reveal peak temperature conditions attained during a subsequent contact overprint. This view was recently challenged by Beyssac et al. (2019) who observed delayed CM recrystallization in the contact aureole of the Ballachulish Complex. They attributed “insufficient” CM recrystallization during contact metamorphism to CM pre-tectonation resulting from preceding regional metamorphism at ~500 °C, and consequently cautioned the use of RSCM thermometry in polyphase metamorphic terrains.

Rooted in an attempt at precisely constraining the thermal history of the plutono-metamorphic Ryoke belt (SW Japan), the present work evaluates the validity and usefulness of RSCM data in a polymetamorphosed terrain. This is done from the point of view of both the first- and second-order Raman spectra of CM, as the latter are only rarely explored and quantified (e.g. Beyssac et al., 2002a, 2019; Nakamura and Akai, 2013). Several decades of structural, petrological and geochronological investigations in the Ryoke belt have provided a comprehensive picture of its tectono-thermal evolution (see Wallis and Okudaira, 2016 for a synthesis). In the Iwakuni-Yanai area (western part of the Ryoke belt), the prominent feature preserved by metasedimentary rocks is a regional metamorphic gradient with increasing Pressure – Temperature ( $P - T$ ) conditions from north to south (e.g. Brown, 1998). On its western flank granitoids generated contact metamorphism *before* the regional overprint, whereas on its eastern flank a later intrusion caused contact metamorphism *after* the regional event (e.g. Skrzypek et al., 2016). This field target therefore offers the opportunity to monitor the response of CM to intermingled contact and regional metamorphic events, and to evaluate the potential of CM for deciphering the thermal evolution of complex metamorphic belts.

## 2. Geological outline of the Iwakuni-Yanai area

The Ryoke belt exposed in the Iwakuni-Yanai area is composed of metasedimentary rocks intruded by numerous granitoids (e.g. Higashimoto et al., 1983; Fig. 1). It formed by polyphase deformation and metamorphism of Triassic to Jurassic accretionary-wedge sediments (Takami et al., 1993) during Cretaceous plutonic activity (e.g. Nakajima, 1994; Nakajima et al., 1990; Wallis and Okudaira, 2016). The metasedimentary rocks presently expose a low- $P$ /high- $T$  metamorphic gradient that increases from north to south (e.g. Brown, 1998) while the lithology evolves from low-grade (meta-) mudstone/sandstone to medium-grade schist and high-grade gneiss (Fig. 1). The surrounding biotite(±amphibole)-bearing granitoids show a dominantly I-type affinity (Nakajima et al., 2016) and belong to the ilmenite series of Ishihara (1977).

Two main deformation phases (DP) are recognized: the DP1 event generated the dominant subhorizontal foliation observed in the gneiss zone while DP2 produced km-scale upright folding in both the schist and gneiss zones (Okudaira et al., 1995; Skrzypek et al., 2016). Pre-DP1 contact metamorphism around the western granitoids is evidenced by the presence of pre-tectonic andalusite and cordierite blasts (Nureki, 1974; Skrzypek et al., 2016; Fig. 1). This was followed by a *syn*-DP1 overprint referred to as regional as it is associated with the growth of foliation-forming parageneses that are used to define E – W trending metamorphic zones (Fig. 1). From north to south Ikeda (1998) defined the chlorite, chlorite–biotite, biotite, muscovite–cordierite and K-feldspar – cordierite zones, with the higher-grade sillimanite–K-feldspar and

garnet–cordierite zones being outside the scope of the present study. Pressure – Temperature conditions – all implicitly ascribed to regional metamorphism – increase from ~450–500 °C/1 kbar in the Chl – Bt and Bt zones to 520–550 °C/1–2.5 kbar in the Ms. – Crd zone and 590–675 °C/1–3 kbar in the Kfs – Crd zone (Ikeda, 2004; Kouketsu et al., 2014b; Sugawara, 2013). Post-DP1 contact metamorphism is locally observed around the granitic intrusion in the eastern part of the study area (Fig. 1).

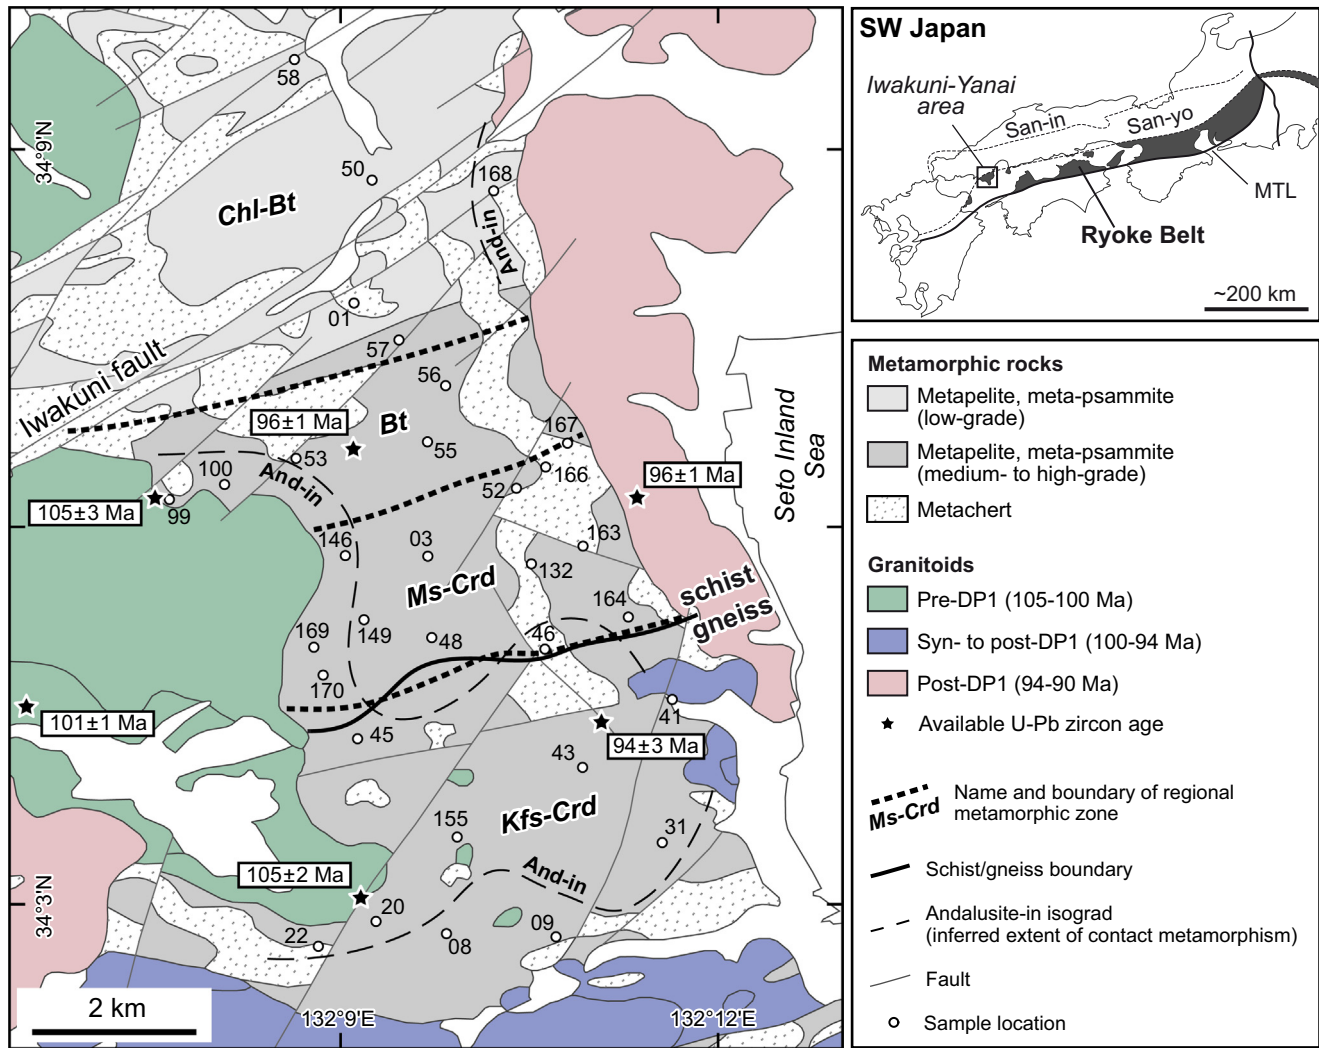

The western granitoids are pre-DP1 intrusions with U – Pb zircon and monazite ages of 105–100 Ma that constrain the first contact metamorphic event (Skrzypek et al., 2016, 2020). The southern granitoids comprise *syn*-DP1 gneissose granodiorite and porphyritic granite emplaced at 100–98 Ma (e.g. Okudaira et al., 1995; Skrzypek et al., 2016), and a post-DP1 quartz diorite emplaced at c. 94 Ma (e.g. Akasaki et al., 2015; Mateen et al., 2019). The post-DP1 eastern granite has a U – Pb zircon age of c. 96 Ma (Skrzypek et al., 2016), and is likely associated with microgranite dykes that are found within the metasedimentary belt and show similar U – Pb zircon ages of c. 96–94 Ma (Skrzypek et al., 2016; Fig. 1). The regional metamorphic event is thought to be coeval with DP1 deformation based on U – Pb dates of 103–97 Ma obtained from metamorphic zircon domains in gneiss samples from the highest grade Grt – Crd zone (Nakajima et al., 2013; Skrzypek et al., 2016). However, monazite dating by different methods provides dates as young as  $89 \pm 5$  Ma in the Kfs – Crd zone (Skrzypek et al., 2018). Recrystallized domains in magmatic monazite from a western granitoid sample yield U – Pb dates between 102 and 91 Ma and similarly suggest the persistence of medium- to high- $T$  conditions until c. 90 Ma (Skrzypek et al., 2020).

## 3. Samples

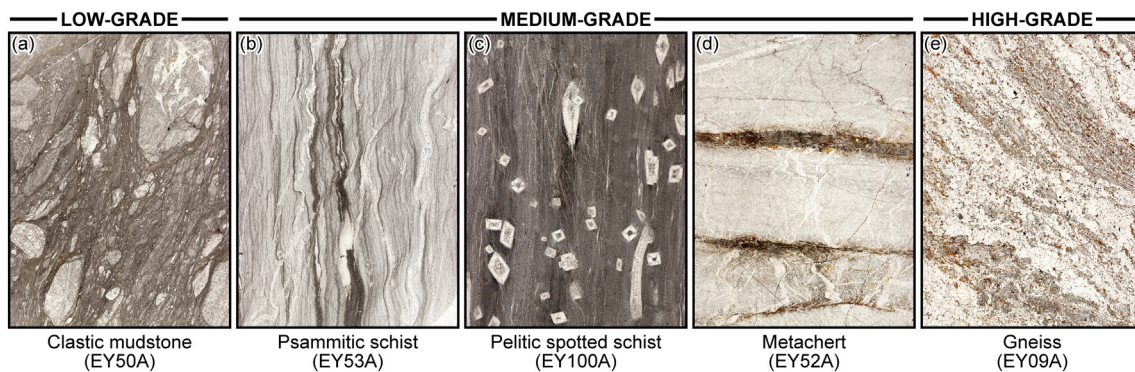

Thirty-two samples were collected from the Chl – Bt to the Kfs – Crd zone (Fig. 1). The rock types comprise weakly metamorphosed mudstone, dark schist, spotted schist, massive hornfels, gneiss and metachert (Fig. 2). The samples can be broadly classified as pelitic, psammitic or siliceous metasediments based on the relative proportions of micas and quartz in thin section. Several samples show features suggesting a contact metamorphic overprint such as mm-scale muscovite or biotite laths, and andalusite or cordierite porphyroblasts (~0.5 cm) (Fig. 2c).

Schistose rocks are fine-grained and preserve the original sedimentary bedding defined by alternating mica- and quartz-rich layers. Micas (Ms ± Bt) grow parallel to the bedding planes and locally define an oblique, spaced cleavage resulting from DP2 folding (Fig. 2b). Gneissose rocks are coarser-grained and exhibit a pervasive metamorphic foliation defined by the alternation of quartz±plagioclase- and biotite-rich layers (Fig. 2e). Pelitic samples correspond to black schist or mica-rich gneiss with relatively abundant CM distributed across the entire thin section (Fig. 2c). Psammitic samples contain thicker Qtz ± Pl-rich layers, and the less abundant CM is mainly present in the mica-rich layers (Fig. 2b). Siliceous samples appear as white or greyish banded metachert at the macroscopic scale; under the microscope they show thick Qtz-rich layers separated by thin mica-rich bands where most of the overall scarcely present CM is observed (Fig. 2d). In all samples CM is dominantly found inside or along the boundaries of the main matrix minerals (Qtz, Ms., Bt, Pl; Fig. 3). Carbonaceous material also forms well-defined inclusion trails in andalusite and cordierite porphyroblasts when present (Fig. 3).

Four different CM textures (I–IV) are distinguished under the microscope. Type I corresponds to a dusty texture of fine-grained, scattered CM particles that are only locally connected to form thin, discontinuous layers (Fig. 3a, b). This texture is observed in low-grade and CM-poor rocks (6 samples). Type II involves fibers and elongated grain clusters of variable thickness that form continuous layers (Fig. 3c, d). Type II is common in schistose, CM-rich lithologies (10 samples). Type III texture is represented by relatively small, scattered grains with an irregular

**Fig. 1.** Geological map of the Ryoke belt in the Iwakuni-Yanai area (SW Japan), with sampling localities. Inset shows the area within the Inner Zone of SW Japan (MTL = Median Tectonic Line). Granitoids are classified according to their emplacement timing relative to the main, regional tectono-metamorphic event (DP1). Available U-Pb zircon ages for granitoids and microgranite dykes (within metasediments) are indicated (Skrzypek et al., 2016). Lithologies are after Sato (1933), Higashimoto et al. (1983) and the Geological Survey of Japan (2012). Metamorphic zone boundaries modified after Ikeda (1993). Schist/gneiss boundary modified after Higashimoto et al. (1983). Mineral abbreviations follow IUGS recommendations after Kretz (1983).

**Fig. 2.** Scans of thin sections illustrating the different rock types, compositions and textures with increasing metamorphic grade. (a) Low-grade (meta-)mudstone with Qtz-rich clasts and abundant CM in the matrix. (b) Medium-grade psammitic schist with thin, CM-rich pelitic layers. (c) Medium-grade spotted schist with chistolite porphyroblasts and abundant CM in the matrix. (d) Medium-grade metachert with thin pelitic layers where Ms-Bt laths, yellowish pinitized Crd porphyroblasts and CM are concentrated. (e) High-grade gneiss with alternating Qtz-Pl and Bt-Crd layers, the latter being richer in CM. The terms low-, medium- and high-grade are used in a relative manner. The bottom edge of scans is about 2 cm.

outline (Fig. 3e, f). Such anhedral grains are commonly observed as inclusions in matrix minerals as well as in mica, andalusite or cordierite porphyroblasts. Type III is found in psammitic rocks with intermediate

amounts of CM (8 samples). Type IV corresponds to coarser, stubby or elongated CM grains that mostly accumulate along the boundaries of matrix minerals (Fig. 3g). Backscatter electron images show that the

**Figure 3.** Photomicrographs (a,c,e,g; plane-polarized light) and backscatter electron images (b,d,f,h,i) illustrating the different textures and morphologies of carbonaceous material. (a,b) Type I (schist sample EY56A) – (a) micro-crenulated, discontinuous trails of tiny CM particles in a Qtz–Ms–Bt matrix; (b) thin oriented CM needles in Bt and Qtz. (c,d) Type II (schist sample EY170A) – (c) weakly folded, nearly continuous layers of elongated CM in the matrix; (d) folded and relatively thick CM laths in a Qtz–Pl–Ms–Bt matrix. (e,f) Type III (metachert sample EY166A) – (e) small and irregular, isolated CM grains in Ms–Bt laths. The larger, rounded opaque minerals are Ilm; (f) thin and short CM laths in micas, Qtz and at grain boundaries. (g,h,i) Type IV (gneiss sample EY09A) – (g) coarse, rounded or irregular CM grains along Pl grain boundaries, next to Bt and inside a Crd porphyroblast. Enlarged views of (h) small CM grains inside Crd and (i) larger CM laths and flakes in the matrix.

matrix CM laths and flakes are markedly larger than CM included in Crd porphyroblasts from the same sample (Fig. 3h, i). Type IV texture is restricted to gneissose rocks from the Kfs – Crd zone (8 samples).

#### 4. The Raman spectrum of carbonaceous material

The Raman spectrum of CM can be divided into a first-order (1000–1700  $\text{cm}^{-1}$ ) and second-order (2300–3300  $\text{cm}^{-1}$ ) region (Fig. 4). In the first-order region the only Raman-active band predicted by group theory is the G band at  $\sim 1580 \text{ cm}^{-1}$  (Fig. 4a), which is ascribed to in-plane atomic displacements ( $E_{2g}$  mode, e.g. Dresselhaus et al., 1977; Tuinstra and Koenig, 1970). All other bands arise from the presence of defects such as point defects (vacancies, impurities) or planar defects (crystal edges, stacking faults) that introduce some “disorder” in the lattice and enhance double-resonant Raman scattering (electron-phonon-defect; Thomsen and Reich, 2000). Such bands are therefore named D bands. Because they result from a resonant process these bands are dispersive; their position, shape and intensity vary with the energy of the exciting laser (e.g. Pócsik et al., 1998; Sato et al., 2006; Sinha and Menéndez, 1990; Vidano et al., 1981). For the samples used in this study, only the D1 ( $\sim 1350 \text{ cm}^{-1}$ ) and D2 ( $\sim 1620 \text{ cm}^{-1}$ ) bands are observed (Fig. 4a). Other authors report the presence of the D'' ( $\sim 1100 \text{ cm}^{-1}$ ), D3 ( $\sim 1500 \text{ cm}^{-1}$ ) and D4 ( $\sim 1200 \text{ cm}^{-1}$ ) bands (see Beyssac and Lazzeri, 2012 for a synthesis of band names).

In the second-order region, overtones or bands due to combination scattering also appear as a result of double-resonant processes (Thomsen and Reich, 2000) and are commonly labeled S (see Henry et al., 2019). The most intense and perhaps most interesting one is the S1 band (also called G' or 2D) at  $\sim 2700 \text{ cm}^{-1}$  (Fig. 4b). Although its position agrees with S1 being the second harmonic of the D1 band (at  $2 \times \sim 1350 \text{ cm}^{-1}$ ), it is even observed in spectra that completely lack the D1 band (Nemanich and Solin, 1979). This is explained by the origin of S1 as a two-phonon resonant band that does not require the presence of defects (electron-two phonons; Reich and Thomsen, 2004). Another consequence of resonant Raman scattering is visible on the S1 band; in mostly two-dimensional (2d) CM the presence of a single electronic band produces only one S1 peak, but the splitting of electronic bands due to interactions between closer graphene layers in three-dimensional (3d) CM causes a splitting of the S1 band (Ferrari et al., 2006; Malard et al., 2009; Fig. 4b) into two peaks at  $\sim 2680 \text{ cm}^{-1}$  (S1-) and  $\sim 2720 \text{ cm}^{-1}$  (S1+). On the one hand, these positions agree with combinations of the G + D'' and D2 + D'', respectively. On the other hand, Ferrari et al. (2006) showed that the D1 band actually contains two peaks at 1340 and 1360  $\text{cm}^{-1}$  whose overtones would precisely be the S1- and S1+ peaks. Two additional bands are observed at  $\sim 2450 \text{ cm}^{-1}$  (S3) and  $\sim 2950 \text{ cm}^{-1}$  (S2); they possibly correspond to combinations of the D1 + D'' and G + D1 bands, respectively (Beyssac and Lazzeri, 2012; Fig. 4b).

#### 5. Analytical procedure

All samples were cut perpendicular to the main foliation, and thin sections of 30  $\mu\text{m}$  thickness were prepared and polished with a 3- $\mu\text{m}$  diamond paste before analysis with a Jasco NRS-3100 Raman spectrometer at Kyoto University. The 532 nm (2.33 eV) beam of a diode-pulsed solid-state (DPSS) laser was attenuated (neutral density filtering with optical density = 1) and focused through a 100 $\times$  objective lens (numerical aperture = 0.95) on the sample ( $\sim 1 \mu\text{m}$  beam diameter). The measured laser power on the sample was about 60  $\mu\text{W}/\text{m}^2$  and a degradation of the CM spectrum during laser irradiation was observed in only rare cases. Reflected and transmitted light observations were used to ensure that the analyzed CM was not exposed at the sample surface. A beam splitter mirror directed the scattered light on a Peltier-cooled ( $-55 \text{ }^\circ\text{C}$ ) CCD detector with 1800 lines/mm grating for a final resolution of about 1  $\text{cm}^{-1}$ . Raman shift was calibrated using the 520.7  $\text{cm}^{-1}$  band of a silicon wafer. It was cross-checked with the 2840, 2883 and 2905  $\text{cm}^{-1}$  bands of polypropylene (Arruebarrena de Báez et al., 1995) before measurements in the second-order region. The spectrometer drift was assessed by measuring the intense emission bands of the built-in Ne lamp before and after each session, and was found to be less than 1  $\text{cm}^{-1}$  within a few hours and about 2  $\text{cm}^{-1}$  for measurements conducted over an entire day.

The first-order spectrum was measured for the window 760–1780  $\text{cm}^{-1}$  and with 4 integrations of 30 s (30–40 spot analyses per sample on different grains). The second-order spectrum was measured for the window 2270–3090  $\text{cm}^{-1}$  and with 3 integrations of 15 s (15 spot analyses per sample on different grains). Because changing the center of the measurement window can alter the Raman shift calibration, the first- and second-order spectra were measured during separate sessions and on different grains, but in the same parts of the thin section.

The raw spectra were processed with Fityk 1.3.1 software (Wojdyr, 2010). For first-order data the background was linearly subtracted between 1255 and 1710  $\text{cm}^{-1}$  and the visible G, D1 and D2 bands were fitted with Pseudo-Voigt functions based on earlier works (e.g. Beyssac et al., 2003b). The different peak parameters (frequency  $\omega$ , intensity  $I$ , area  $A$ , shape  $s$ ) were exported to calculate mean and standard deviation values for each sample (Table 1, see Supplementary Material for the full dataset). The shape parameter  $s$  depicts the relative Gaussian ( $s = 0$ ) and Lorentzian ( $s = 1$ ) contributions in the Pseudo-Voigt function (see Wojdyr, 2010). The G peak has a mean  $s$  close to 1 indicating that a Lorentzian fit could be sufficient. Conversely, D1 commonly shows  $s = 0.5$ , which might reflect the actual presence of two peaks (Ferrari et al., 2006) and accounts for its frequent asymmetrical shape. For second-order data the background was linearly subtracted between 2320 and 3020  $\text{cm}^{-1}$  and the visible S1, S2 and S3 bands were fitted with Lorentzian functions (Fig. 4b). Lorentzian functions were chosen to limit the degree of freedom for peak fitting; only  $\omega$ ,  $I$  and the half

**Fig. 4.** Typical Raman spectra of CM for the low- to high-grade samples analyzed in the present study. (a) First-order region with the dominant G band and the defect-induced D1 and D2 bands. (b) Second-order region with S1, S2 and S3 bands. The S1 band has a single peak in low-grade samples but splits into two distinct peaks (S1- and S1+) in medium/high-grade ones. Dashed lines show fitting of the split S1 band by two Lorentzian functions.

Abund. = relative CM abundance in thin section; Morph. = morphological type of CM.

T<sub>CM</sub> calculated from R2 ratios with the calibration of Aoya et al. (2010) for a 532 nm laser.

Results for low- and high-grade (Low/High) subgroups of analyses are shown for indication.

width at half maximum can be varied in this case, whereas the additional  $s$  parameter is available for a Pseudo-Voigt function. This was chosen in agreement with previous works (e.g. Cançado et al., 2008) and because the main objective was to measure the splitting of S1 without the possible influence of differing shapes for the S1+ and S1- peaks.

The main Raman parameters that will be discussed are defined as follows: R1, dimensionless intensity ratio =  $[I_{D1}/I_G]$ ; R2, dimensionless area ratio =  $[A_{D1}/(A_{D1} + A_{D2} + A_G)]$ ;  $\Delta S1$ , absolute frequency difference in  $\text{cm}^{-1} = [|\omega_{S1+} - \omega_{S1-}|]$ ; RS1, dimensionless intensity ratio =  $[I_{S1-}/I_{S1+}]$ . Temperatures ( $T_{CM}$ ) were calculated using R2 ratios and the relationship derived for contact metamorphism by Aoya et al. (2010) because it is the only calibration available for a 532 nm excitation wavelength. Its quadratic equation gives temperatures that are 10 °C lower (at low-grade) but up to 28 °C higher (at high-grade) than those obtained with the calibration of Beyssac et al. (2002a).

## 6. Results

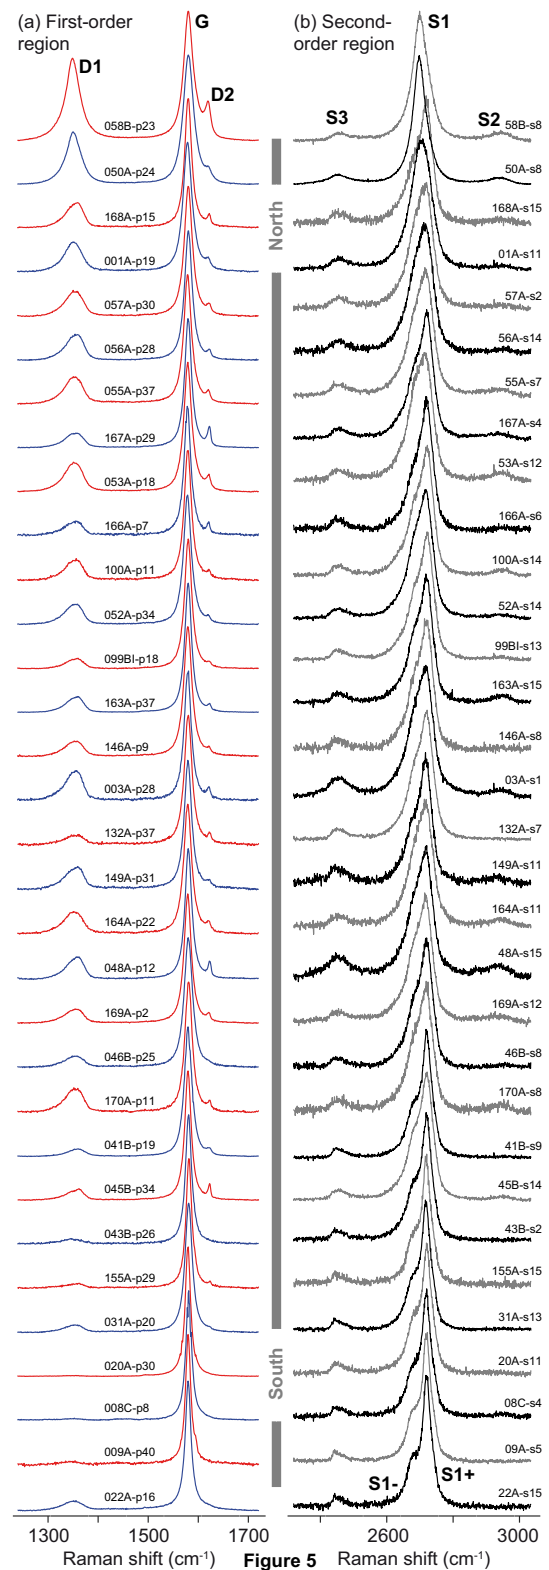

### 6.1. First- and second-order regions of the Raman spectrum

The intense G band dominates the first-order spectrum of CM in all samples (Fig. 5a). It is accompanied by the D1 and D2 bands whose intensities decrease from north to south while G becomes narrower. The D1 band evolves from a symmetrical peak slightly higher than half of the G band to a smaller asymmetrical peak, and eventually disappears (Fig. 5a). The narrow and less intense D2 band clearly appears on the high frequency shoulder of the G band in low-grade samples but vanishes in high-grade ones (Fig. 5a). In high-grade samples the proportion of spectra without any “disorder” band ranges from 35 to 78% of all analyzed spectra (Table 1). The R1 and R2 ratios are uncorrelated with the pelitic, psammitic or siliceous composition of the samples (Table 1). They are partly linked with CM texture as low ratios are generally obtained from type IV CM, which is only found in high-grade gneiss samples.

The second-order spectrum is dominated by the S1 band, with the less intense S2 and S3 bands appearing on each side of it (Fig. 5b). The two northernmost samples (EY58B, EY50A) exhibit a single S1 band centered at  $\sim 2700 \text{ cm}^{-1}$ . In all other samples S1 splits into the S1- and S1+ peaks whose frequency difference  $\Delta S1$  increases from north to south (Fig. 5b). Two low-grade (EY01A, EY57A) and one medium-grade (EY48A) sample preserve mixed results with a larger proportion of spectra showing the double S1 band and a few having a single S1 band (Table 1). The broad and low-intensity S2 band tends to shrink with rising metamorphic grade but does not entirely disappear in high-grade samples. The intensity of the weak S3 band does not significantly change with increasing metamorphic grade, but its shape becomes more asymmetrical (Fig. 5b). Like the R1 and R2 ratios, the RS1 and  $\Delta S1$  parameters do not show any correlation with pelitic, psammitic or siliceous sample compositions; they are partly linked with CM texture in the case of type IV CM from high-grade gneiss (Table 1).

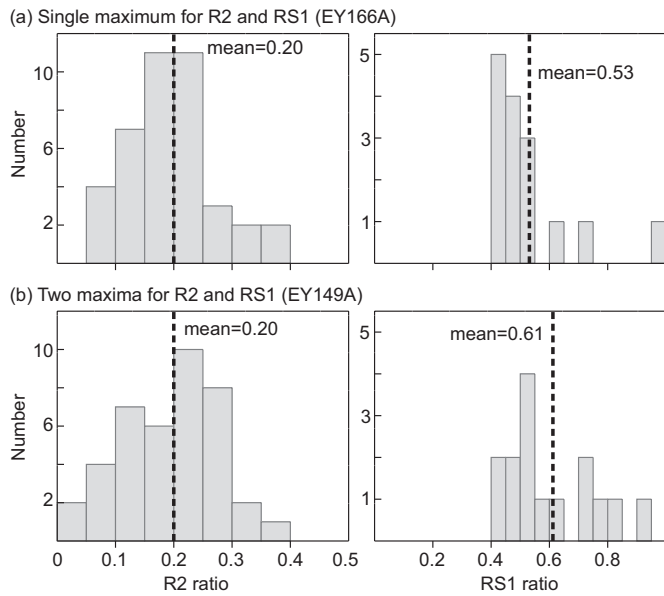

### 6.2. Intra-sample variation of Raman parameters

The variability of Raman parameters in each sample was assessed using the R2 and RS1 ratios (see Supplementary Material). In all samples the mean of R2 data converges towards a constant value for more than 20–30 analyses while that of RS1 becomes nearly constant above  $\sim 10$  analyses. In high-grade samples, where first-order spectra devoid of “disorder” bands are common, a total of 30 analyses was sufficient to reach a constant mean for R2. The acquisition of 30–40 first-order and 15 second-order spectra was therefore sufficient to confidently characterize R2 and RS1 in a sample. This difference in the number of first- and second-order spectra that needed to be acquired is mostly explained by larger intra-sample variations in the area of the D1 band.

**Fig. 5.** Representative first- and second-order Raman spectra of CM for all samples, sorted from north to south (spot names indicated). (a) First-order region with defect-induced bands decreasing and eventually disappearing towards the south. (b) Second-order region with the transition from single S1 to double S1- and S1+. Vertical intensity scale is arbitrary. Raw spectra are trimmed to show only the relevant regions.

Histograms of R2 and RS1 distribution were also inspected to detect the presence of multiple CM populations. For most samples the distribution of R2 and RS1 defines a single maximum, and the mean of R2 or RS1

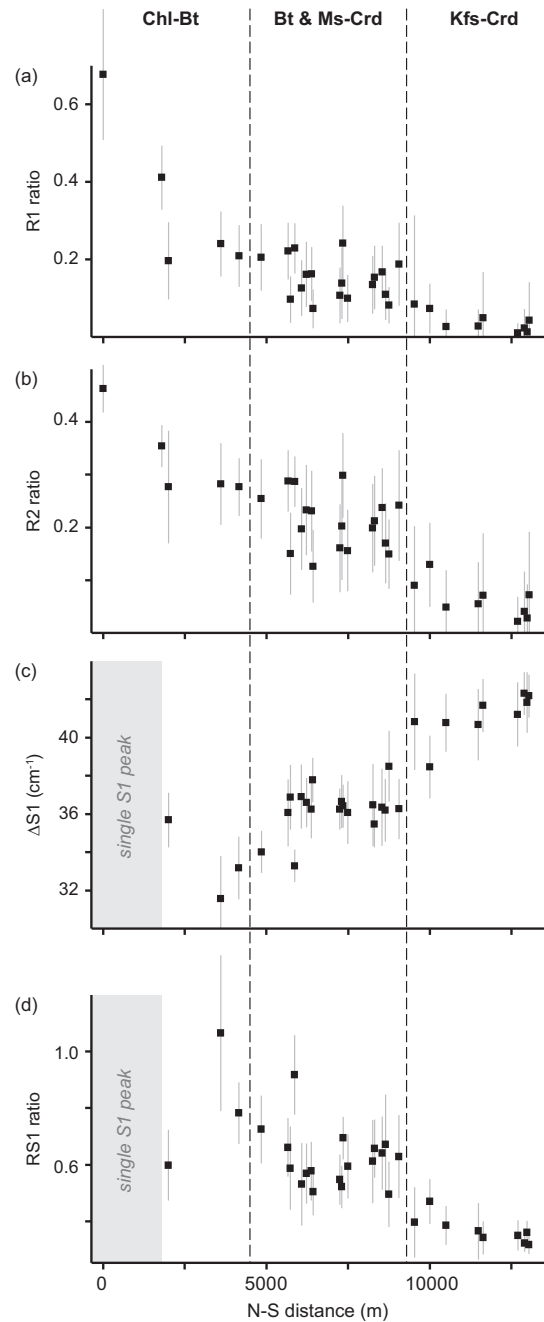

**Fig. 6.** Histograms of R2 ( $n = 40$ ) and RS1 ( $n = 15$ ) distribution in two samples with similar mean R2 values (0.20) to illustrate differences in the variability of first- and second-order Raman parameters. (a) Sample EY166A with a single maximum for both R2 and RS1 distributions. Each mean value matches the maximum of the distribution. (b) Sample EY149A with a slightly bimodal distribution of both R2 and RS1. Although a low- and high-grade group can be distinguished, the final dataset uses the mean of all analyses (see text and Table 1).

coincides with the maximum of its frequency distribution (Fig. 6a). Samples for which a contact metamorphic overprint is inferred (i.e. with porphyroblasts) tend to show broader R2 distributions but preserve only one CM population. For three samples (EY53A, EY132A, EY149A), however, a bimodal distribution of both R2 and RS1, and the observation that mean R2 and RS1 values rather lie in between two maxima may suggest the presence of two CM populations (Fig. 6b). In these samples a low- and high-grade group can be distinguished, but no correlation with the shape or location (e.g. matrix vs. inclusions in porphyroblasts) of CM grains is apparent. The difference between both groups is also not as extreme as in cases where mixing of metamorphic and detrital CM is inferred (e.g. Kouketsu et al., 2019). In order to describe the spatial variation of Raman parameters, such sub-populations are therefore ignored and a mean value for the whole sample is used (Table 1).

### 6.3. Spatial variation of Raman parameters

In first-order spectra the intensity of the D1 and D2 bands decreases from north to south (Fig. 5a). This translates into a decrease of both R1 (0.68 to 0.01) and R2 (0.46 to 0.02) ratios and a concomitant increase in calculated temperature  $T_{CM}$  (425 to 659 °C) along the exposed metamorphic gradient (Fig. 7a,b, Table 1). In the Bt and Ms–Crd zones  $T_{CM}$  also increases towards the west and east as samples approach the surrounding granites (Fig. 8a). It is depicted by a large scatter of R1 (0.07–0.24) and R2 values (0.13–0.30) in this segment of the N-S transect (Fig. 7a, b). In map view the variation of  $T_{CM}$  defines a relatively low- $T$  domain ( $T_{CM} < 535$  °C) to the north of the Iwakuni fault. This domain narrows to the south of the Iwakuni fault but persists up to the schist/gneiss boundary in the axial part of the metasedimentary belt (Fig. 8a). It is surrounded by a medium- $T$  domain ( $535 < T_{CM} < 600$  °C) close to the granitoids and the schist/gneiss boundary while a high- $T$

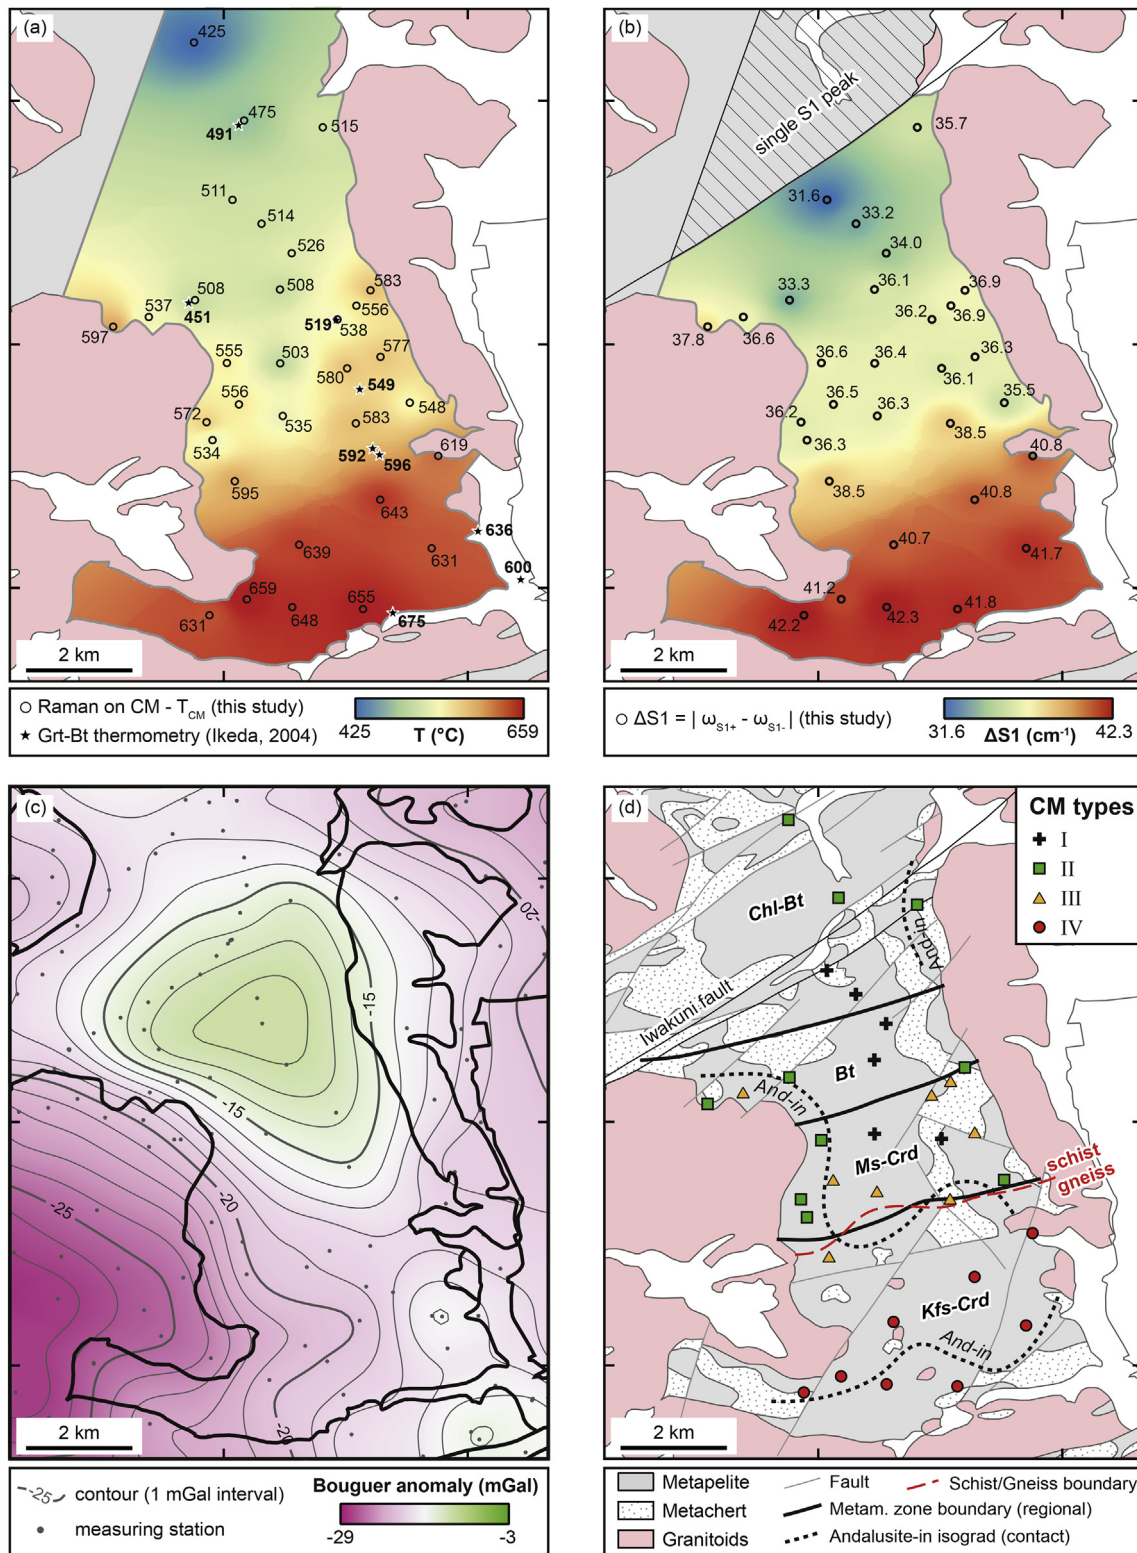

**Fig. 7.** Evolution of selected first- and second-order Raman parameters from north to south. (a–b) Gradual decrease of the first-order R1 and R2 ratios. (c–d) Stepwise variation of the second-order  $\Delta S1$  and RS1 parameters (calculated for a split S1 band). The error bar reflects the standard deviation of all measurements in a sample. The boundaries of metamorphic zones are indicated.

domain ( $T_{CM} > 600$  °C) occurs in gneissose rocks from the Kfs–Crd zone (Fig. 8a).

The major change in the second-order spectra is related to the splitting of the S1 band. The two northernmost samples exhibit a single S1 band, whereas all other samples show mostly or exclusively the two S1- and S1+ peaks (Fig. 5b). From north to south the intensity of S1+ increases with respect to that of S1- ( $RS1 = 1.06$  to 0.32) and the spacing  $\Delta S1$  between these peaks increases (31.6 to 42.3  $\text{cm}^{-1}$ ) in a rather stepwise manner (Fig. 7c,d). In map view the variation of  $\Delta S1$  defines three domains delimited by NE–SW- to E–W-trending boundaries; no

**Fig. 8.** Spatial distribution of selected Raman parameters, and comparison with gravity anomaly data and the metamorphic structure of the Iwakuni-Yanai area. (a) Map distribution of  $T_{CM}$  calculated with the R2 ratio. Black stars and bold numbers show the results of Grt-Bt thermometry (Ikeda, 2004) for comparison. (b) Map distribution of  $\Delta S1$  ( $\Delta S1 = 0$  north of the Iwakuni fault). (c) Bouguer anomaly map (2.67 g/cm<sup>3</sup> terrain correction) for the extent of the study area (Geological Survey of Japan, 2013; Komazawa, 2013, and references therein). (d) Lithological map with the main features generated by contact (And-in isograd) and regional (mineral zones) metamorphism (Higashimoto et al., 1983; Ikeda, 1998; Skrzypek et al., 2016), and with the distribution of CM textural types. The interpolated maps for  $T_{CM}$  and  $\Delta S1$  were calculated with the same parameters (see Appendix).

splitting of the S1 band is observed to the north of the Iwakuni fault, a domain of lower  $\Delta S1$  (32–38 cm<sup>-1</sup>) broadly coincides with the schist zone and one of higher  $\Delta S1$  (>38 cm<sup>-1</sup>) with the gneiss zone

(Fig. 8b). Parameters calculated for the S2 and S3 bands do not show any clear trend, except for the full width at half maximum of S3 that slightly decreases (~60 to 40 cm<sup>-1</sup>) from north to south.

## 7. Geological significance of RSCM data

### 7.1. Interpretation of results from first-order Raman spectra

#### 7.1.1. Pre-DP1 contact metamorphism

A domain of medium  $T_{CM}$  values (535–600 °C) is imaged along the western granitoid that intrudes the schist zone (Fig. 8a). This domain closely follows the contact aureole defined by the occurrence of pre-DP1 andalusite porphyroblasts (Skrzypek et al., 2016; Fig. 8d). This temperature range is typical for andalusite appearance in pelitic lithologies affected by contact metamorphism (e.g. Pattison and Tracy, 1991) and indicates that RSCM confidently reveals the thermal effect of pre-DP1 contact metamorphism, as already shown by several studies of metamorphic aureoles (e.g. Aoya et al., 2010; Nakamura and Akai, 2013). The narrow width of the thermal aureole (< 1 km), despite a subhorizontal contact with metasediments, additionally points to a relatively low host-rock temperature at the time of intrusion.

A prolongation of the aureole in the gneiss zone was proposed based on the presence of the western granitoids at shallow depth beneath metasedimentary rocks, although the pre-DP1 origin of andalusite blasts is hard to establish there (Skrzypek et al., 2016; Fig. 1). It can be supported by the gravity anomaly map (Komazawa, 2013, and references therein) that correlates well with the inferred extent of the entire aureole (Fig. 8c, d). The values for  $T_{CM}$  in the gneiss zone (> 600 °C) are, however, markedly higher than in the north and seem to result from the subsequent regional overprint. An argument for the regional origin of these high  $T_{CM}$  is the dominant occurrence of coarser-grained type IV CM in the gneiss zone (Fig. 8d), whereas this type is never observed in the north, even in a sample located at the contact with a granite where  $T_{CM}$  reaches 597 °C (EY99BI; Table 1). This suggests that a different heating event was necessary to generate the CM texture and crystallinity observed in the gneiss zone.

#### 7.1.2. Syn-DP1 regional metamorphism

Apart from peripheral domains of the schist zone where  $T_{CM}$  exceeds ~535 °C, the axial part of the belt shows  $T_{CM}$  increasing from ~425 to 535 °C (Fig. 8a). Following a gap at the schist/gneiss transition, the gneiss zone exhibits homogeneously higher  $T_{CM}$  values of ~600–660 °C associated with coarser-grained type IV CM (Fig. 8a). The entire succession agrees with the Grt-Bt thermometry results of Ikeda (2004) for samples located away from the influence of granitoids (compare results on Fig. 8a); combined temperature estimates indicate 450–500 °C for the Chl – Bt zone, 500–525 °C for the Bt zone, 500–535 °C for the Ms. – Crd zone and 600–660 °C for the Kfs – Crd zone (Ikeda, 2004; Table 1). Both RSCM and Grt-Bt thermometry therefore constrain the well-known N-S regional metamorphic gradient that has also been described in other parts of the Ryoke belt (e.g. Hokada, 1998; Kawakami, 2001; Miyazaki, 2010).

#### 7.1.3. Post-DP1 contact metamorphism

The eastern granite intrudes only the schist zone and its boundary with metasedimentary rocks is subvertical. Its contact aureole is not easily mapped due to the presence of abundant siliceous lithologies and is only traced in the north (Fig. 8d). The spatial distribution of  $T_{CM}$  nevertheless reveals a wide domain of medium temperatures (540–580 °C) along the southern border of the granite (Fig. 8a). A post-DP1 contact metamorphic origin is inferred for this domain, as its outline does not follow the regional metamorphic zones, and because a limited extension of the eastern granite towards the SW is consistent with gravity anomaly data (Fig. 8a,c). Regardless of the intrusion that caused the temperature increase, this case demonstrates the usefulness of RSCM data for identifying thermal overprints in petrologically “inappropriate” lithologies and for tracing the extent of buried magmatic bodies. These aspects have already been emphasized with XRD (e.g. Tsuchiya et al., 1987) as well as RSCM (e.g. Hilchie and Jamieson, 2014) data. If the heating event occurred after regional metamorphism,

the possibility for delayed CM recrystallization (Beyssac et al., 2019) must be discussed. This is done in Section 8 with the help of both first- and second-order Raman data.

### 7.2. Interpretation of results from second-order Raman spectra

Unlike for  $T_{CM}$ , the evolution of the S1 band defines three domains separated by E – W trending boundaries. A single S1 peak north of the Iwakuni fault zone is followed by a weak to mostly moderate  $\Delta S1$  in the schist zone and a higher  $\Delta S1$  in the gneiss zone (Fig. 8b). This pattern is parallel to the E – W trending metamorphic zones produced by the regional overprint, whereas an increase in  $\Delta S1$  towards the surrounding granitoids is not evident (Fig. 8b). It strongly suggests that the second-order S1 band records the effect(s) of the regional tectono-metamorphic event DP1.

The transition from a single to double S1 band occurs across the Iwakuni fault zone (Fig. 8b). For XRD data available along the same transect, a sharp decrease in the full width at half maximum ( $\beta$ ) of the (002) peak in CM from 0.40–0.83° to less than 0.36° is reported across the fault (Ikeda, 1992). Grew (1974) and Itaya (1981) document the same drastic drop in  $\beta$  when the C content of CM increases above 90–97%, in agreement with the commonly observed decrease of H – N – O – S in CM with metamorphic grade (Izawa, 1968; Wada et al., 1994). It therefore appears that the expulsion of non-C elements, some of them being known to impede graphitization (e.g. Franklin, 1951), is responsible for the splitting of the S1 band.

The splitting of the second-order S1 band is explained by the electronic band structure of CM; a single S1 peak reflects the absence of electronic interaction between graphene layers, whereas a double S1 peak points to interlayer interaction as the graphene planes become closer to each other and acquire regular ABAB stacking (e.g. Ferrari et al., 2006). The mineralogical significance is that 2d CM acquired a 3d structure south of the Iwakuni fault. Increasing  $\Delta S1$  values towards the south indicate that the 3d structure still evolved, i.e. that both interlayer spacing ( $d_{002}$ ) decreased and out-of-plane ordering increased to a maximum value of 42.3 cm<sup>-1</sup> (sample EY08C). For comparison, the average  $d_{002}$  in the Kfs – Crd zone is 3.358 Å (Ikeda, 1992) while Lespade et al. (1984) report maximum values of  $\Delta S1 \approx 45$  cm<sup>-1</sup> and  $d_{002} \approx 3.355$  Å for heat-treated graphitizing carbon ( $d_{002} = 3.3539$  Å for ideal graphite; Kwicińska and Petersen, 2004).

## 8. General implications for RSCM

### 8.1. S1 band splitting and the 500 °C isotherm

In the study area, the splitting of S1 occurs together with a hardly detectable lithological transition from weakly-metamorphosed sediment to schist (Higashimoto et al., 1983), for  $T_{CM}$  between 475 and 511 °C (Fig. 8a), and across a pressure change from 0.8 to 1.9 kbar (difference between the Chl – Bt and Ms. – Crd zones; Kouketsu et al., 2014b). The splitting of S1 is consistently observed above 2200 °C in heat-treated industrial graphite (Bernard et al., 2010; Pimenta et al., 2007; Wilhelm et al., 1998), but a higher pressure and longer heating duration are also able to shift the S1 band to a higher frequency in experiments conducted at 1000 °C (Beyssac et al., 2003a). For metapelites from different metamorphic belts Wopenka and Pasteris (1993) report a shift of the S1 band above chlorite grade, i.e. for  $P - T$  conditions higher than 500 °C/4 kbar (Pasteris and Wopenka, 1991). Using an extensive sample set Beyssac et al. (2002a) observe the splitting of S1 above ~500 °C without any apparent link with pressure. In the Gyoja-yama contact metamorphic aureole (Japan), Nakamura and Akai (2013) show that the S1 band splits between 510 and 530 °C. The change from a single to a double S1 band was also recognized between 495 and 500 °C in the Nelson aureole, Canada (Beyssac et al., 2019).

The review of data highlights that the splitting of S1 always occurs at about 500 °C regardless of lithology, pressure or tectonic setting.

Accordingly, temperature is considered to be the major factor influencing the splitting of S1, hence the appearance of 3d CM in metamorphic rocks. Nakamura (1995) also recognized that a  $\beta$  value of  $0.3^\circ$  was consistently attained at  $500^\circ\text{C}$  in both regional and contact metamorphic settings. The present study therefore emphasizes that a simple, visual comparison of second-order spectra is a powerful approach to locate the  $500^\circ\text{C}$  isotherm in metamorphic terrains and to approximately distinguish between H–N–O–S-bearing and C-richer carbonaceous material.

### 8.2. Applicability of RSCM thermometry: Delayed CM recrystallization or not?

Along the SW margin of the eastern granite a medium-temperature domain is ascribed to post-DP1 contact metamorphism (Fig. 8b). This interpretation requires explaining why no delayed CM recrystallization is observed as in Beysac et al. (2019). A first possibility is that the heating event was not younger than regional metamorphism. However, the occurrence of 96–94 Ma-old microgranite dykes up to the centre of the metasedimentary belt (Fig. 1) and the gravity anomaly map (Fig. 8c) support a small extension of the eastern granite at depth, and back the post-DP1 origin of the thermal overprint. A second possibility is that the presence/absence of delayed recrystallization depends on the crystallinity of the CM precursor.

Observations from the present study rather agree with those of Delchini et al. (2016) who showed that samples regionally metamorphosed at  $\sim 560^\circ\text{C}$  were still able to record  $T_{\text{CM}}$  of  $616\text{--}628^\circ\text{C}$  due to subsequent contact metamorphism (their samples J2a and J2.5a). The only place where  $T_{\text{CM}}$  is somewhat lower than expected lies at the northern margin of the eastern granite. There, sample EY168A records  $T_{\text{CM}} = 515^\circ\text{C}$  although the presence of andalusite blasts could hint at a slightly higher temperature, like in the western aureole (Fig. 8a). Beysac et al. (2019) estimate pre-intrusion regional temperatures of  $\sim 500^\circ\text{C}$  in the Ballachulish Complex, i.e. conditions at which CM is still far from ideal graphite. A similar difference exists between the northern and southern margins of the eastern granite;  $\Delta S1$  in the northern Chl–Bt zone is low ( $< 36\text{ cm}^{-1}$ ) and points to limited 3d ordering, whereas constant and higher  $\Delta S1$  values in the Bt and Ms–Crld zones indicate increased 3d ordering, likely acquired during regional metamorphism (Fig. 7c).

In the light of available data, it therefore appears that CM recrystallization during a subsequent thermal overprint is, at least in part, controlled by the 3d structure of the CM precursor. Should 3d CM, yet with still low out-of-plane ordering ( $\Delta S1 < 36\text{ cm}^{-1}$ ), be thermally overprinted then could the elimination of in-plane defects remain sluggish and lead to a discrepancy with other thermometric estimates (e.g. Beysac et al., 2019). Conversely, thermal overprinting of CM with better 3d ordering ( $\Delta S1 \geq 36\text{ cm}^{-1}$ ) would more efficiently remove in-plane defects and provide reliable RSCM temperature estimates (e.g. Delchini et al., 2016; this study). It is similarly expected from transmission electron microscope observations that in-plane crystallite growth can further proceed once stacked graphene layers have reached a sufficient degree of out-of-plane ordering (e.g. Rouzaud et al., 1983).

### 8.3. Discrepancy between first- and second-order Raman data

A key result of the study is the partial discrepancy between first- and second-order Raman data, namely R2 and  $\Delta S1$  (Fig. 9). The distribution of R2 and associated  $T_{\text{CM}}$  partly matches the extent of contact metamorphic aureoles, whereas that of  $\Delta S1$  follows the regional metamorphic zones (Fig. 8a,b). The question is whether  $\Delta S1$  values are lower or higher than expected for a local  $T_{\text{CM}}$ .

From the Iwakuni fault to the schist/gneiss boundary, a north-south profile in the axial part of the belt reveals increasing  $\Delta S1$  from  $\sim 33$  to above  $36\text{ cm}^{-1}$ , whereas  $T_{\text{CM}}$  remains nearly constant at  $\sim 510^\circ\text{C}$  (Fig. 8a,b). Conversely, a west-east profile in the Bt and Ms–Crld zones shows that  $\Delta S1$  stays constant ( $\sim 36\text{ cm}^{-1}$ ) while  $T_{\text{CM}}$  increases from

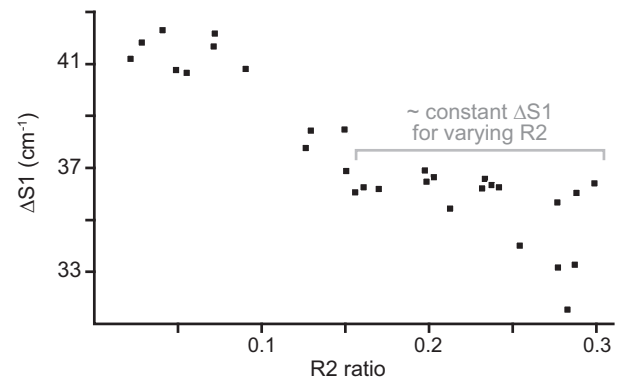

Fig. 9. Plot of  $\Delta S1$  vs. R2 for samples south of the Iwakuni fault, i.e. with a split S1 band ( $n = 30$ ). Note the spread of R2 values for samples having a nearly constant  $\Delta S1$  of  $\sim 36\text{ cm}^{-1}$ .

$\sim 500$  to  $600^\circ\text{C}$  towards the surrounding granitoids (Fig. 7b,c). This indicates that  $\Delta S1$  is higher than expected for the  $T_{\text{CM}}$  values obtained in the axial part of the belt, where the influence of contact metamorphism is thought to be weaker. A similar behaviour is observed with the XRD data of Ikeda (1992); from north to south the out-of-plane crystallite size  $L_c$  increases throughout the Chl–Bt zone ( $\sim 100$  to  $230\text{ \AA}$ ) but clusters at a constant value in the Bt and Ms–Crld zones ( $\sim 280\text{ \AA}$ ; Fig. 10a). A west-east profile across the Bt and Ms–Crld zones reveals uniform  $L_c$  values despite varying  $T_{\text{CM}}$ , with a noticeable  $L_c$  increase only close to the eastern granite (Fig. 10b).

All observations call for a process that could generate homogeneous  $\Delta S1$  and  $L_c$  values without a proportional impact on R2 and  $T_{\text{CM}}$ . The  $\Delta S1$  parameter relates to the out-of-plane structure of CM (e.g. Beysac and Lazzeri, 2012; Cançado et al., 2008; Ferrari et al., 2006), and Lespade et al. (1984) found a correlation between increasing  $\Delta S1$  and decreasing interlayer spacing  $d_{002}$ . Similarly, the out-of-plane length of coherent crystallites  $L_c$  is calculated using the XRD value of  $\beta$ , which can be regarded as a measure of out-of-plane distortion of the graphene layers (Fischbach, 1970). Conversely, R2 involves the area of “disorder” bands in the first-order Raman spectrum, which arises from the presence of in-plane defects in CM (e.g. Ferrari and Robertson, 2000). The intensity of defect-induced bands was also shown to decrease with increasing in-plane crystallite size  $L_a$  (e.g. Knight and White, 1989; Tuinstra and Koenig, 1970). In other words, factors that can lead to homogeneous out-of-plane ordering despite variable in-plane crystallinity must be sought.

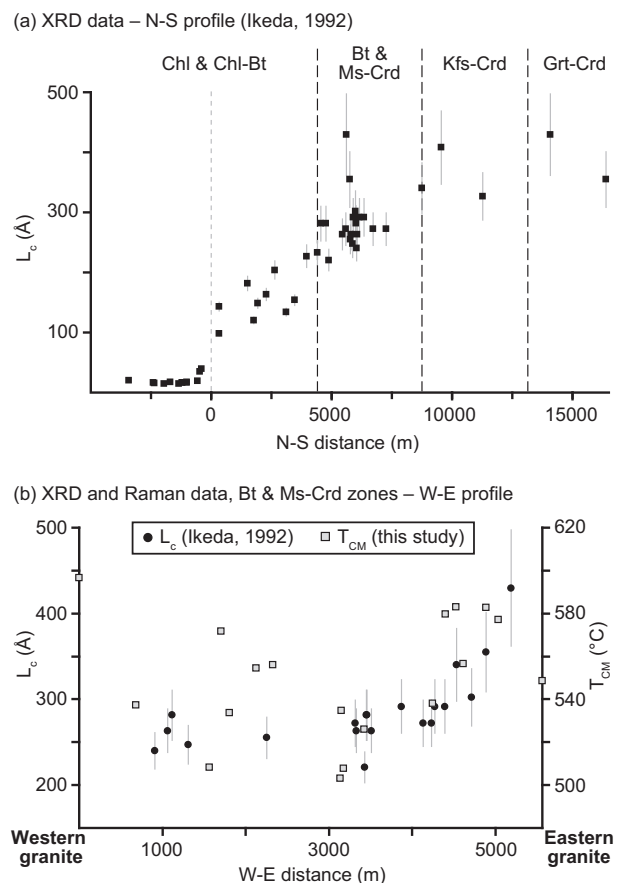

#### 8.3.1. Nature of CM precursor

Numerous works have emphasized that the degree of graphitization depends on the nature of the CM precursor (e.g. Franklin, 1951; Inagaki, 1996; Rouzaud and Oberlin, 1989). For example, heat treatment of deposited carbon films results in faster and more complete graphitization for thick films compared to thin ones (Rouzaud et al., 1983). Different CM textures are recognized in the area, with relatively thin CM type I being found in the axial part of the belt and thicker type II occurring next to granitoids (Figs. 3a–d, 8d). This difference likely arises from pre-D1 contact metamorphism and could have led to contrasted graphitization during subsequent tectono-thermal events, but it cannot account for the uniform  $\Delta S1$  and  $L_c$  values observed in the Bt and Ms–Crld zones.

#### 8.3.2. Fluids

Fluids are invoked to explain the presence of CM with unusually low or high crystallinity in metamorphic rock samples. On the one hand, variable or unexpectedly low CM crystallinities were partly attributed to the presence of fluid with high methane (Wintsch et al., 1981) or low oxygen (Large et al., 1994) fugacity, which limited the graphitization process. On the other hand, CM grains found in greenschist facies rocks but indicating higher temperatures were explained by the

**Fig. 10.** Evolution of XRD and Raman data along N-S and W-E profiles. (a) N-S variation of crystallite thickness  $L_c$  (Ikeda, 1992). The error bars reflect the  $0.03^\circ$  standard deviation ascribed to  $\beta$  by Ikeda (1992) and propagated in the calculation of  $L_c$ . Note that the extent of the profile is larger than for the present Raman dataset. (b) Comparison of  $L_c$  (Ikeda, 1992) and  $T_{CM}$  (this study) data for the Bt and Ms-Crd zones, as a function of W-E position.

precipitation of higher-crystallinity (lower R2) CM from hydrothermal fluids (Křibek et al., 2008). The circulation of C-bearing fluid is particularly well evidenced by the pervasive network of quartz veins oblique or parallel to the regional schistosity in the Bt and Ms-Crd zones (Mateen et al., 2015; Terabayashi et al., 2010). This could have promoted deposition of highly crystalline hydrothermal graphite and could explain the high R2 values observed next to granitoids, but not the discrepancy between  $\Delta S1$  and R2.

### 8.3.3. Heating duration

Mori et al. (2017) showed that short-lived ( $10^2$  years) heating by less than 100 m-thick intrusions can noticeably decrease the R2 ratio of CM but is not sufficient to reach steady-state CM crystallinity. Steady state appears to be attained in contact metamorphic aureoles around larger plutons, with modelled heating time scales of about  $10^5$  years (e.g. Hilchie and Jamieson, 2014). Nakamura et al. (2017) additionally attempted to extrapolate the kinetics of graphitization for a sample from the Hidaka belt (NE Japan), a high- $T$  area similar to the Ryoke belt. Their figure 11 indicates that, at  $\sim 500^\circ\text{C}$ , the  $d_{002}$  of ideal graphite is attained much faster ( $10^6$  years) than the complete elimination of in-plane defects ( $>10^8$  years). These experimental results could suitably explain the discrepancy between higher out-of-plane and lower in-plane crystallinity.

### 8.3.4. Pressure

Both tectonic stress and lithostatic loading have a unit of pressure. As such, they are able to decrease the microporosity of natural CM and

assist graphitization (e.g. Blackman and Ubbelohde, 1962; Bonijoly et al., 1982; Deurbergue et al., 1987; Nakamura et al., 2020; Noda and Inagaki, 1962; Ross and Bustin, 1990). Beyssac et al. (2003a) similarly shows that S1 band splitting is favored by higher hydrostatic pressure or longer heating duration. Previous geobarometry in the study area documents distinct steps in pressure between the Chl-Bt ( $\sim 1$  kbar), Ms-Crd ( $\sim 2$  kbar) and Kfs-Crd ( $\sim 2.5$  kbar) zones (Kouketsu et al., 2014b), which could explain the stepwise increase of the out-of-plane parameters  $\Delta S1$  and  $L_c$  (Figs. 7c, 10a). The DP1 phase was associated with the foliation-parallel growth of metamorphic minerals in both the schist and gneiss zones, which also points to pervasive tectonic stress, in agreement with the recognition of regional flattening strain patterns in the area (Okudaira et al., 2009; Okudaira and Beppu, 2008).

### 8.3.5. Energetic considerations

An important result of some TEM studies about graphitization is that the transformation of CM starts with  $L_c$  increase followed by  $L_a$  increase (e.g. Rouzaud et al., 1983; Rouzaud and Oberlin, 1989). This is explained by the energy required to remove interstitial defects being lower than that required for the coalescence of adjacent crystallites and the removal of in-plane defects. Of the factors discussed above, only heating duration and pressure (1) provide additional energy during graphitization and (2) operate at a regional scale. However, a longer heating duration will tend to durably change both in-plane and out-of-plane CM crystallinity (Nakamura et al., 2017). Therefore, it is likely a combination of moderate temperature ( $\sim 500^\circ\text{C}$ ), non-protracted heating ( $10^6$  years) and increased pressure (tectonic stress and/or lithostatic loading) that can explain the discrepancy between first- and second-order Raman data. These conditions were met on a regional scale in the Bt and Ms-Crd zones during the DP1 event.

## 9. Conclusions

A Raman spectroscopy study of carbonaceous material affected by successive contact and regional metamorphic events reveals that the combination of first- and second-order spectra can help constraining the tectono-thermal history of complex metamorphic terrains.

- As a complement to RSCM thermometry based on the first-order spectrum, a rapid inspection of the second-order S1 band should allow tracing the  $500^\circ\text{C}$  isotherm and distinguishing between H-N-O-S-bearing (single S1) and C-richer (split S1) CM in metamorphic belts.
- RSCM thermometry is able to confidently reveal the influence of post-regional contact metamorphism. Delayed CM recrystallization can alter this potential, and likely depends on the crystallinity of the regionally-metamorphosed CM precursor.
- The  $\Delta S1$  parameter is calculated from peak splitting of the second-order S1 band; in addition to graphitization temperature,  $\Delta S1$  appears useful for tracing regional variations in heating duration and pressure.

### Declaration of Competing Interest

None.

### Acknowledgements

I would like to express my warmest thanks to K. Yoshida for having introduced me to the different aspects of Raman spectroscopy. Boundless support from T. Hirajima and T. Kawakami during my stay in Kyoto is also acknowledged. T. Kawakami kindly provided sample YN31. M. Takaya is thanked for thin section preparation. I wish to thank T. Ikeda for sharing his views on the Ryoke belt. The study benefited from funding by the Japanese Society for the Promotion of Science (JSPS post-doctoral fellowship to E.S.; JSPS grant No. 25-03715 to T. H.). D.

Gallhofer and C. Hauzenberger are thanked for reading an early version of the manuscript. Critical assessment of a previous version of the manuscript by two anonymous referees, review comments by Y. Kouketsu and Y. Nakamura, and editorial handling by M. Scambelluri are kindly acknowledged.

## Appendix A. Parameters used for interpolated maps of $T_{CM}$ and $\Delta S1$

Interpolated maps of  $T_{CM}$  and  $\Delta S1$  presented in Fig. 8a, b were calculated with the same parameters for direct comparison. Interpolation was performed with the inverse distance weighting method (GRASS GIS module v.surf.idw; GRASS Development Team, 2017) and the following input parameters: number of interpolation points = 10 (out of 32 for  $T_{CM}$  and 30 for  $\Delta S1$ ), power parameter = 2 (squared weighting), output pixel size = 45 m (~1/100 of the average distance between data points).
