We have experimentally realized Brewster’s effect for transverse-electric waves with metamaterials. In dielectric media, Brewster’s no-reflection effect arises only for transverse-magnetic waves. However, it has been theoretically predicted that Brewster’s effect arises for TE waves under the condition that the relative permeability $\mu_r$ is not equal to unity. We have designed an array of split-ring resonators as a metamaterial with $\mu_r \neq 1$ using a finite-difference time-domain method. The reflection measurements were carried out in a 3-GHz region and the disappearance of reflected waves at a particular incident angle was confirmed.

Brewster’s no-reflection condition is one of the main features of the laws of reflection and refraction of electromagnetic waves at a boundary between two media. For a specific incident angle, known as the Brewster angle, the reflection wave vanishes. In dielectric media, this phenomenon exists only for transverse-magnetic (TM) waves ($p$ waves), and not for transverse-electric (TE) waves ($s$ waves). It is conveniently applied in optical instruments. One can generate completely polarized light from an unpolarized light source only with a glass plate. It can also be used to avoid the reflection losses at the surfaces of optical components. The Brewster window of the discharge tube in gaseous lasers is a typical example.

For a plane electromagnetic wave incident on the plane boundary between medium 1 and medium 2, the amplitude reflectivities of TE and TM waves are given by the Fresnel formulas:

$$r_{\text{TE}} = \frac{\sin(\theta_i - \theta_r)}{\sin(\theta_i + \theta_r)}, \quad r_{\text{TM}} = \frac{\tan(\theta_i - \theta_r)}{\tan(\theta_i + \theta_r)},$$

where $\theta_i$ and $\theta_r$ are the angles of incidence and transmission, respectively.¹ The numerators in Eq. (1) cannot vanish because $\theta_i$ is not equal to $\theta_r$. However, $r_{\text{TM}}$ can vanish because $\tan(\theta_i + \theta_r)$ diverges to infinity when $(\theta_i + \theta_r)$ is equal to $\pi/2$.

Physically, Brewster’s phenomena can be understood as follows. The direction of the induced electric dipole in medium 2 is perpendicular to the wave vector therein. With regard to TM waves, the dipole lies in the plane of incidence. A linearly vibrating dipole radiates transversally and cannot emit radiation in the direction of the vibration. This direction coincides with the wave vector of the reflected wave when the Brewster condition is satisfied. The oscillating dipoles in medium 2 do not send any waves in the direction of the reflection. On the other hand, with regard to TE waves, each dipole is perpendicular to the plane of incidence and emits waves isotropically in the plane. Therefore, no special angles exist for TE waves. (The dipole model also explains the sign change in the amplitude reflectivity when the angle is changed through the Brewster angle.)

Brewster’s effect in dielectric media exists only for TM waves, and not for TE waves. This asymmetry results from the assumption that the relative permeability $\mu_r$ is almost unity for higher frequencies, such as microwaves and light waves. Each medium is characterized only by its relative permittivity $\varepsilon_r$. The assumption that is used in deriving Eq. (1) is quite reasonable because for common materials, any kind of magnetic response is frozen in high-frequency regions. However, the assumption must be reconsidered for metamaterials, for which both $\varepsilon_r$ and $\mu_r$ can be changed significantly from unity. Brewster’s effects in general cases such as magnetic, anisotropic, and chiral media have been studied²⁻⁴ and no-reflection phenomena for those, other than TM waves, have been predicted. The use of metamaterials for verifying these generalized Brewster effects has been suggested.⁵⁻⁷ In this report, we demonstrate the Brewster effect for TE waves in magnetic metamaterials experimentally.

A metamaterial is composed of small conductive elements such as coils or rods, upon which currents are induced by the incident electric or magnetic fields. When their sizes and separations are significantly smaller than the wavelengths, the collection of elements can be viewed as a continuous medium. By utilizing resonant structures, both $\varepsilon_r$ and $\mu_r$ could be significantly shifted from unity. In particular, a medium with $\varepsilon_r < 0$ and $\mu_r < 0$ attracts attention because of its peculiar behavior owing to the negative index of refraction $n = \sqrt{-\varepsilon_r \mu_r}$. (Ref. 8). Negative refraction has been experimentally confirmed in the microwave and terahertz regions.⁹⁻¹¹

An artificial medium with $\varepsilon_r = 1$, $\mu_r \neq 1$, which is a dual of normal dielectric materials, $\varepsilon_r \neq 1$, $\mu_r = 1$, can be designed. Magnetic dipoles are induced by the magnetic field of the incident wave. Repeating the discussion with the dipole model, one can conclude that Brewster’s effect can be observed for TE waves in the case of such magnetic metamaterials.

We assume that medium 1 is a vacuum and medium 2 is a medium with $\varepsilon_r$ and $\mu_r$. The amplitude reflectivities for TE and TM waves are expressed as follows:
The no-reflection conditions, where the Brewster condition for TE waves can be realized, exist for a medium that is more magnetic, rather than electric, in order to realize the Brewster condition for TE waves. In other words, the Brewster angle can be determined for a given pair, \( (\mu_r, \varepsilon_r) \). Theoretical derivations of the Brewster angles for general media have been presented in previous works.\(^3\)\(^-\)\(^7\) With this equation, the Brewster angle can be determined for a given pair, \((\mu_r, \varepsilon_r)\). In Fig. 1(c), the Brewster angles are plotted parametrically on the \((\mu_r, \varepsilon_r)\) plane. Based on the inequalities of Eq. (3), we see that the Brewster angle for TM waves exists only in the shaded area in Fig. 1(c). By exchanging the roles of \(\varepsilon_r\) and \(\mu_r\), we obtain the Brewster condition for TE waves as indicated by the unshaded area in Fig. 1(c).

It is apparent that Brewster’s effect arises only for TM waves in normal media (\(\mu_r = 1\)). However, for a medium with \(\mu_r \neq 1\), the Brewster condition for TE waves can be realized. For a given \(\mu_r \neq 1\), when \(1/\mu_r \leq \varepsilon_r \leq \mu_r\) is satisfied, there exists a Brewster angle for TE waves. In other words, the medium must be more magnetic, rather than electric, in order to realize the Brewster condition for TE waves.

We consider an array of split-ring resonators (SRRs), as shown in Fig. 2(a). It serves as a magnetic medium with \(\mu_r \neq 1\) in microwave regions.\(^1\)\(^2\) Each SRR functions as a series resonant circuit formed by the ring inductance and the inter-ring capacitance. When we apply time-varying magnetic fields through the ring, a circular current around the ring is induced near the resonance frequency so that it produces a magnetic moment. Owing to the resonant structure, the effective permeability \(\mu_e\) could be significantly different from unity.

We calculate the relative complex permittivity \(\varepsilon_r\) and permeability \(\mu_r\) of the SRR array using a finite-difference time-domain (FDTD) method.\(^1\)\(^3\) We consider a rectangular SRR, as shown in Fig. 2(b), for the purpose of simplicity in calculation. Assuming that a plane wave is incident on the SRR array, we analyzed the charge distribution and the induced current, from which the electric and magnetic dipole moments originate. The permeability \(\varepsilon_r\) (permeability \(\mu_r\)) can be derived from an electric (magnetic) dipole moment of a single SRR and the density of the SRRs.\(^1\)\(^4\)

Figure 3 shows \(\varepsilon_r\) and \(\mu_r\) as functions of frequency \(f\). The real parts of \(\varepsilon_r\) and \(\mu_r\) are related to the dispersive or refractive properties of metamaterials, and the imaginary parts are related to the losses or absorption. As seen in Fig. 3, the permittivity can be regarded as unity for any frequency, and \(\text{Re}(\mu_r)\) and \(\text{Im}(\mu_r)\) can be approximated by the Lorentz dispersion and absorption functions. The ratio of the maximum value of \(|\varepsilon_r(f) - 1|\) to that of \(|\mu_r(f) - 1|\) is less than 2%. The electric response of SRR is much weaker than the magnetic response.
The separation between the two aluminum plates is 38 mm (=0.38λ₀).

response especially for the electric field in the direction of the symmetric axis of reflection. This fact agrees with previous studies.15,16 The SRR array functions as a magnetic medium with finite losses. We also found that the inductor-capacitor liquid crystal (LC) circuit model is helpful in the estimation of the resonance frequency.

The reflectivity at the Brewster angle for the SRR array, unlike an ideal medium without losses, has a nonzero value due to the dissipation. If the dispersive property of the magnetic medium dominates the dissipation, we can detect a significant depression in the power reflectivity around the Brewster angle. In order to estimate the magnitude of the depression, we introduce the ratio of the minimum power reflectivity, R₀ and the reflection angle equal to the incident angle θ. We arranged the SRRs orthogonally to make the response of the SRR array isotropic. The dimension of the SRR array is (W, D, T) = (135 cm, 45 cm, 38 mm) = (13.6λ₀, 4.5λ₀, 0.38λ₀). In order to ensure an extended boundary, we set the width W to be significantly larger than λ₀. We made the depth D sufficiently large so that the influence of the back side reflection can be avoided.

First, we measured the transmissivity of the SRR array in order to determine the resonance frequency f₀, which was found to be 2.65 GHz; it was 12.8% smaller than the value calculated with the LC circuit model.

We used a network analyzer as the microwave generator and detector. We connected a horn antenna (the aperture size is 15 cm × 3.4 cm) to the transmitting port of the network analyzer in order to transmit a slowly diverging beam. We use another horn antenna connected to the receiving port in order to receive the plane wave reflected at the boundary. Only the plane wave propagating normal to the antenna aperture can be coupled to the receiver. We always set the direction of the receiving horn antenna such that a plane wave reflected with a reflection angle equal to the incident angle is detected.

We measured the θ dependence of the power reflectivity for a fixed frequency. One of the results is shown in Fig. 5(a). Compared to the case of perfect reflection, the reflectivity decreases by more than 27 dB in the vicinity of θ = 60°, which corresponds to the Brewster angle for TE waves.

We measured the frequency dependence of the Brewster angle. The result is shown in Fig. 5(b) (solid circles). The Brewster angles could be determined only in a limited region

FIG. 4. Schematic of the reflectivity measurement system. Measurement is performed in a 2D waveguide composed of two aluminum plates. The separation between the two aluminum plates is 38 mm (=0.38λ₀).

FIG. 5. (a) Power reflectivity of the SRR array at f = 2.6001 GHz as a function of θ. (b) Measured (solid circle) and calculated (dashed line) Brewster angles vs frequency.

(=0.13λ₀) in the z direction. The direction of H varies in the xy plane because the power reflectivity is measured for various incident angles θ. We measured the SRRs orthogonally to make the response of the SRR array isotropic.
just below the resonance frequency. In this region, the measured Brewster angles increase with the frequency. We calculated the frequency dependence of the Brewster angles from Eq. (2) by assuming \( \varepsilon_r(f) = 1 \) and \( \mu_r(f) = 1 - F(f^2 + i\gamma f - f_0^2) \), where \( f_0 = 2.65 \) GHz is the resonance frequency that is previously determined by the absorption measurement. By fitting the calculated values to the measured values, we fixed the parameters \( F \) and \( \gamma \). The calculated angle is shown as the dashed line in Fig. 5. It increases with frequency; this is in agreement with the experimental results.

As previously discussed, we can observe the Brewster angles only in a limited frequency region. It should be noted that in actual experiments, the reflectivity varies somewhat erratically due to the interference of spurious waves or other reasons, and the dip in reflectivity can be detected only for the cases where \( R_{\text{min}}/R_0 \) is sufficiently small. In the other on-resonance frequency regions, \( R_{\text{min}} \) cannot be sufficiently small due to the absorption losses. On the other hand, \( R_0 \) reduces in the off-resonance regions.

In conclusion, we observed Brewster’s effect for TE waves, which had previously never been observed for normal dielectric media. We need a medium whose \( \mu_r \) is not equal to unity. We have used a metamaterial composed of SRRs in order to achieve a magnetic medium in a microwave region. This is a good example of the use of metamaterials. In terms of the parameter space \( (\mu_r, \varepsilon_r) \), by introducing metamaterials, the rigid condition of \( \mu_r = 1 \) can be eliminated. The restrictions \( \varepsilon_r > 0 \) and \( \mu_r > 0 \) can also be eliminated. The working range of metamaterials presently extends from microwaves to terahertz or even to optical regions. In the near future, we may be able to fabricate a Brewster window for TE light.
