Flux Pinning in Nb-Ti based Nanoscale Superconducting Multilayers

Hidetaka Oguma, Kozo Osamura, Akira Sakai, Hiroaki Otsuka and Ikuo Ito

Abstract—Nanoscale Nb-Ti/Nb/Cu-Ni-Si-Zn multilayers have been fabricated by means of a plastic deformation technique where a precipitation - hardening copper alloy was used. When the thickness dependence of the global pinning force was examined at constant magnetic fields, it increased monotonically with increasing Nb-Ti layer thickness at 5 T from 4.8 to 120 nm, but it showed a maximum at 24 nm at 1.5 T. The critical temperature (T_c) decreased with decreasing thickness when the layer thickness was smaller than 20 nm. The present experimental results suggested that the major flux pinning is attributed to the superconducting/normal interface and the proximity effect resulted in the degradation of T_c .

Index Terms— artificial pinning, Nb-Ti alloy, nano-scale multilayer, proximity effect

I. INTRODUCTION

A high performance magnetic shield composed of superconducting materials is used for the magnetic shielding at high magnetic fields and for the severe magnetic shielding. The principle is explained as follows. The magnetic flux density becomes zero at the distance from the surface $d_p = B / (\mu_0 J_c)$ when the external magnetic field (B) penetrated in the superconducting sheet. Accordingly, the use of thinner shielding sheet is possible when the sheet has higher critical current density (J_c). Also the good mechanical deformability is requested for fabricating a complicated shielding container, for instance. At present, Nb-Ti composite superconducting sheets are the best materials for magnetic shielding.

The commercial Nb-Ti sheets have fairly high critical current density [1], where the ribbon - like Ti precipitates act effectively as magnetic flux pinning centers. Due to the precipitation treatment, the maximum volume fraction of Ti precipitates is only limited up to 25 % [2]. In order to realize higher critical current density, an increase of number density of pinning sites is highly desired. One of several relevant ideas is to create artificial pinning centers (APC). The thin Nb filaments are embedded regularly and densely in the Nb-Ti matrix along the wire [3]. Those Nb filaments behave like dots

in the cross section perpendicular to the wire axis. From their geometrical arrangement, they are called island type APC. The other is called lamella type APC. Two Nb-Ti and Nb sheets are stacked mutually, and then mechanically pressed and cut to get strips. Their strips are composed to the round wires [4]. Till now, many efforts have been concentrated to fabricate the wires with APC. Our research subject, however, is to improve the superconducting sheets. The simple idea is to design the multilayer of superconducting (SC)/normal (N) sheets, by which the volume fraction of superconductor can reach to 50 %. The optimum pinning force, however, can be theoretically explained in terms of the ratio of coherence length and the ratio of layer thickness between the SC and the N layers. The quantitative calculation has been performed elsewhere [5]. Further it is easy to control the period and structure of multilayers in order to realize the best shielding performance for a given magnetic field.

In the present study, we fabricated the nanoscale multilayer sheets by means of the thermomechanical technique and investigated their superconducting properties as well as microstructure.

II. EXPERIMENTAL PROCEDURE

The Nb-Ti(d_s)/Nb(d_b)/Cu-alloy(d_n) multilayers were fabricated by using the thermomechanical treatment technique, where d_s , d_b and d_n are the layer thickness and the ratio $d_s/d_b/d_n$ was kept constant as 10/1/10. As shown in Fig. 1, a fundamental assembly consisted of Nb-46.5%Ti(0.8mm) / Nb(0.05mm) / Cu alloy(0.8mm) / Nb(0.05mm) unit, where the original thickness of each sheet is indicated in the parentheses. A Cu sheet (8mm) was inserted after every 30 stacks of the above unit. The thickness of the total assembly was 66.2 mm. Here the chemical composition of Cu alloy was Cu-3%Ni-0.6%Si-0.2%Zn (in mass %), which has been the best selection for obtaining nanoscale homogeneous multilayer. The present alloy is known as Corson alloy used to the age-hardenable high conductivity metal. After casing them in the Cu container and pressing at room temperature, the composite was hot-rolled at 1073 K to 34 mm thickness sheet and then cold-rolled to 0.2 mm thickness. Following the cold-rolling process, several samples were annealed at 773 K for 7.2ks. These are designated annealed samples hereafter in the present paper. The other samples were not annealed. Then all the thin samples were cut into small square plates with dimensions of 15 mm x 20 mm. The thin plates were stacked 20 times and cased in the Cu container. This assembly was hot-pressed at 823 K for 7.2 ks under vacuum.

Fig. 1 Assembly of the starting stack of multilayer sheets

Finally the plate was cold-rolled to get thin sheets with thickness between 20 and 100 μm . Due to the present process, the final layer thickness of Nb-Ti was designed from 120 nm to 4.8 nm.

In order to assess the microstructure, TEM and SEM observations were carried out. The transport critical current measurements were carried out under external magnetic fields up to 8 T at liquid helium temperature. The critical current (I_c) was determined with criterion of 1 $\mu\text{V}/\text{cm}$ for the two type of samples where the current direction was parallel (L) or perpendicular (C) to the rolling direction. The magnetic field was applied parallel to the tape surface and perpendicular to the current direction. The critical current density (J_c) was defined as I_c/S , where S is the cross sectional area of the whole sample. The global pinning force (F_p) was calculated as $F_p = J_c B$. The critical temperature (T_c) was measured by means of the inductive technique.

III. EXPERIMENTAL RESULTS AND DISCUSSION

Due to the present procedure, the reduction ratio of thickness reached maximumly 1.8×10^5 . Fig. 2 shows the microphotograph of the cross section of the multilayer sheet, that was designed as the thickness of Nb-Ti layer was 24 nm. The well developed layered structure can be observed. From the similar photos, each layer thickness of the Nb-Ti and Cu alloy was measured where the data of Nb-Ti layer thickness are listed in TABLE I. The observed thickness was found to be nearly identical with the designed value with coefficient of variation less than 0.23.

TABLE I
Designated and observed Nb-Ti layer thickness

Sample Name	Designated Layer Thickness (nm)	Observed NbTi Layer Thickness (nm)	COV
A1-4	40	43.3	0.21
A1-5	20	19.7	0.23

Fig. 2 Cross section of the multilayer sheet along to the rolling direction for the sample with 24 nm Nb-Ti layer thickness.

This indicates that the present thermomechanical treatment is suitable to manufacture the nanoscale multilayer.

Fig. 3 shows the change of critical temperature as a function of the designed layer thickness. With the Nb-Ti layer thickness was reduced from 120 to 30 nm, the critical temperature gradually decreased. A rapid decrease was observed when the thickness became lower than 20 nm, due to the proximity effect. The layer thickness dependence of critical temperature was evaluated for the present multilayer structure [6], where the change of order parameter was calculated based on the quantum mechanical theory and the critical temperature is estimated as a function of order parameter in the Nb-Ti layer. The calculated result shows that the critical temperature is constant with decreasing layer thickness up to 15 nm and then rapidly decreased to zero below 10 nm. When comparing with the theoretical result, the decreasing rate was moderate, because the layer thickness distributes in practice and the proximity effect is averaged over the layers with different thickness.

Fig. 3 Change of critical temperature as a function of the designated layer thickness.

Fig. 4 Comparison of the direction of applied magnetic field for the global pinning force for the samples with different Nb-Ti layer thickness, where C and L indicate the magnetic field perpendicular and parallel to the cold-rolling direction, respectively.

The global pinning force was compared for two samples with C and L directions taken from the same multilayer sheets as shown in Fig. 4, where two cases with different Nb-Ti layer thickness are shown. The samples with 96 nm thick showed the maximum nearly at 4 T, while the global pinning force of the C's sample was always larger than that of the L's one. For the sample with 24 nm thick, the maximum appeared at the lower magnetic field less than 2 T. The difference between two samples of C and L was more enhanced. Their result might be attributed to the directional dependency of work inhomogeneity, that is, the so-called sausageing takes place more frequently along the rolling direction. The critical current ($I_c = SJ_c$) is controlled at the minimum cross section when J_c is constant.

Fig. 5 Change of global pinning force for the L direction as a function of magnetic field for the annealed samples with different layer thickness.

Fig. 6 Change of global pinning force as a function of layer thickness for the C's samples.

Change of global pinning force has been assessed as a function of Nb-Ti layer thickness as shown in Fig. 5 for the annealed samples. When the layer thickness is larger than 70 nm, the maximum appears at around 4 T. On the other hand, the maximum position shifted toward the lower magnetic field and reached the magnetic field between 1 and 2 T for the samples with the thinner layer thickness. The same tendency has been observed for the behavior of global pinning force for the C's samples.

Fig. 6 shows the change of global pinning force as a function of layer thickness for the C's samples. At a constant magnetic field of 5 T, the global pinning force decreased monotonically with decreasing layer thickness. For 1 T, the global pinning force started to increase when the layer thickness decreased below 40 nm. Then it reached a maximum at 35 nm. For 1.5 T, the maximum value of $F_{p,max}$ became highest of 12 GN/m³ for the specimen with Nb-Ti layer thickness of 24 nm. The global pinning force decreased largely to zero at the layer thickness less than 20 nm.

The global pinning force due to the direct summation is proportional to the number density of pinning sites (N_p), the interaction volume (V) and the square of thermodynamic critical field (B_c). The B_c is given as a function of the critical temperature. The layer thickness dependency of their quantities is schematically expressed as shown in Fig. 7. They have the respective characteristic thickness, where the layer thickness dependency changes. Here we consider their change at 1 T. When the external magnetic field is applied parallel to multilayer interface, the layer thickness necessary to obtain the maximum pinning sites geometrically corresponds to $a/4$, where a_i is the lattice constant of the magnetic flux lattice. It is 49 nm for 1 T. The interaction volume is constant at the large layer thickness, but it decreases when d is smaller than 2ξ ,

where the coherence length ξ is supposed to be 5.5 nm for Nb-Ti alloys.

Fig. 7 Schematic representation on the layer thickness dependence of global pinning force at a constant magnetic field.

As shown in Fig. 3, T_c is observed to decrease prominently at d_T , that was about 20 nm. Thus the layer thickness dependence of F_p can be qualitatively given as shown in Fig. 7. The maximum of F_p will appear at the layer thickness, at which the critical temperature starts to decrease. The decrease of T_c depends on the proximity effect. When the proximity effect is reduced, the d_T should shift towards the thinner thickness and the improvement of global pinning force can be expected.

IV. CONCLUSION

The Nb-Ti/Nb/Cu-alloy multilayers have been successfully fabricated by using the thermomechanical treatment technique.

In order to obtain homogeneous multilayers, the use of precipitation hardening type copper alloy was important. The thickness of Nb-Ti layer was reduced minimumly up to 4.8 nm. The global pinning force increased monotonically with increasing layer thickness at 5 T. On the other hand, it became highest at 24 nm when the magnetic field of 1.5 T was applied. The critical temperature decreased with decreasing layer thickness when it was smaller than 20 nm. The present experimental results suggested that the maximum of global pinning force is given as a cross over of the increasing number density of pinning sites and the decreasing critical temperature due to proximity effect.

ACKNOWLEDGMENT

The authors express their thanks to Messrs. I Nakagawa and T.Unezaki for their help about the microstructure analysis.
