(Received 5 May 2003; accepted 28 July 2003)

We report a method for transporting foreign substances into a desired living cell through the use of laser trapping. A single giant DNA molecule can be delivered into a cytoplasmic space if the DNA is folded into a compact state. We also find that microparticles of zeolite are very effective as a vehicle for transferring foreign compounds into a living cell by optical manipulation. © 2003 American Institute of Physics. [DOI: 10.1063/1.1613356]

The transport of specific foreign substances into a targeted cell is an indispensable procedure in medical science and genetic engineering. However, the only method that is currently available for selective transport into individual cells is micro-injection using a micropipette.^{1,2} For example, in genetic engineering, the insertion of chromatin from a differentiated somatic cell into an oocyte using a micropipette is a widely used technique to obtain cloned cells.³ A similar technique is used in fertility treatment. Although the micropipette method is a powerful tool, great skill is necessary for successful manipulation. As an alternative method, a high-power laser has been applied in cell biology, where a focused laser is used to make a pore on a cell membrane by local heating.^{4,5} With this method, foreign species in the external solution flow into the cell in a passive manner. In the present study, we applied the methodology of laser trapping to the transport of a foreign substance into a desired cell, as a potentially automated procedure.⁶

The infrared laser used for optical trapping was a Nd:yttrium–aluminum–garnet laser (SL902T, Spectron), with a TEM₀₀ beam at a wavelength of 1064 nm. The laser beam was reflected by a dichroic mirror, and focused by an objective lens (Nikon, ×100, numerical aperture=1.30) with a microscope (Nikon, TE-300). The beam power was 100–500 mW, as calibrated just before the objective lens of the microscope by a laser power meter (Neoark, PM-345). Experiments on optical delivery and measurements of the trapping efficiency with various particles were performed on the earlier laser trap microscope with a micro-motion horizontal stage (SIGMAKOKI). Ginkgo leaf cells and cabbage protoplasts were used as the recipients. The cabbage protoplasts were prepared by a modified enzyme method using an

enzyme cocktail containing 15 g/l Cellulase ONOZUKA (Yakult, Co. Ltd.), 2 g/l Pectoliase Y-23 (Kikkoman, Co. Ltd.), 3 mM MES [2-(*N*-Morpholino) ethanesulfonic acid], 10 mM CaCl₂ · 2H₂O and 0.5 M sorbitol.⁷ The delivered substances were double-stranded T4DNA (Nippon Gene) and the calcium-detecting fluorescent dye fura-2 (Molecular Probes). The multivalent cation PEG-A, a polyethylene glycol derivative with 8.3 amino-pendent groups (MW=3900) was synthesized as reported previously.⁸ T4 DNA molecules, 0.6 μM in base pairs, were collapsed into a compact state by PEG-A (6 μM in amino group concentration). As a delivery vehicle to promote a higher trapping efficiency, we used zeolite particles [Na₅₆ (Al₅₆Si₃₆O₃₈₄) · 250H₂O, Toyosoda, Co. Ltd.] ground with a mortar and pestle as a carrier.

Table I compares the trapping efficiencies for different objects: a polystyrene bead with a radius of 0.1 μm a ground zeolite particle (radius of around 0.2 μm) and a folded compact DNA (~hydrodynamic radius)⁹ under 200 μM spermidine. In this table, the trapping efficiency Q is represented as $F=nQP/c$, where F , n , P , and c are the trapping force, refractive index of the surrounding medium, beam power, and light velocity, respectively. The trapping efficiencies were evaluated based on the drag speed of trapped objects under the assumption of Stokes friction.¹⁰

Figure 1 shows the injection of a single T4 DNA molecule into a ginkgo leaf cell by laser transport. In this case,

TABLE I. Trapping efficiency of submicrometer-sized particles.^a

Trapping efficiency Q (10^{-3}) ^c	
Compact T4DNA ^b	0.075 ± 0.025
Fluorescent bead	0.80 ± 0.10
Zeolite particle	2.80 ± 0.10

^aThe medium values of 36 experimental trials are given.

^bDNA was compacted by spermidine.

^cThe extinction ratio of trapping laser was assumed as 0.5.

FIG. 1. Optical delivery of a single DNA molecule into a ginkgo leaf cell, where the DNA is compacted by PEG-A. Upper pictures are black-white inverted images, and lower ones are the corresponding schematics. (a) A compact T4 DNA complex with PEG-A is optically grasped. (b) The compact DNA is optically transported toward the cell surface. (c) Delivery of the DNA into the cytoplasm.

T4 DNA is folded into a compact state by forming a complex with PEG-A. It has been reported that individual giant DNA molecules can be optically trapped when they are folded into a compact state using suitable condensing agents.¹¹ The ability to trap DNA molecules stably suggests that it may be possible to apply optical manipulation to the microinjection of DNA into living cells. However, in experiments on compact DNAs, we found that the probability of the successful transport of DNA into a cell was not high (only a few % in several trials). The difficulty in these experiments is due to the weak optical force for grasping compact DNA, as indicated in Table I.

Therefore, we sought a better method for optically driven transport into a living cell. As shown in Table I, the ability of laser-tweezers to grasp a zeolite particle is much greater than its ability to grasp compact DNA molecules. The higher efficiency for zeolite is based on its permittivity for 1064 nm light. Although bigger zeolite particles, larger than several microns, have higher trapping efficiencies, they often absorb laser beam photons, which induces flashing evaporation of the medium. Thus, we used micron-sized particles for optical delivery.

Zeolite particles can hold foreign chemicals in their fine pores. Figure 2 shows the transport of a zeolite particle doped with a fluorescent dye, fura-2, into a protoplast cell. After the particle is delivered, emission from fura-2 complexed with intracellular calcium ion is observed [Fig. 2(b)], indicating that the particle is indeed transferred into the cytoplasmic space.

This optically driven transport method may have many practical applications. Compared to the current methodologies, transport by laser trapping should cause less damage to living cells. In addition, laser manipulation is suitable for remote control by a computer, i.e., the system can be fully automated, unlike other methods such as micropipetting.¹² As the mechanical force that can be applied by laser trapping is less than that possible in micropipetting even with the use of a vehicle such as zeolite, it is of importance to improve the efficiency. One promising approach to improve the efficiency is to spin the objects using optical force. For example, the rotary motion of a trapped object induced by optical pressure¹³ could promote the efficacy of optical delivery through the membrane into the cytoplasm similar to drilling into a hard wall. Another benefit of optical trapping is that it does not require physical contact with the sample and surrounding substrates. The laser beam passes through the glass

or plastic transport plate glass. This feature could be beneficial under sealed conditions such as in a microflow channel or in microfabrication. Using a laser, an object can be transported to any location on the stage, whereas the application of micropipetting is much more limited. Optical tweezers can be used to transport desired particles within a fully sealed microchannel.¹⁴

In conclusion, the present results suggest that laser trapping may be useful in the field of cell biology, when combined with the use of a suitable carrier such as zeolite. It may be useful to identify or develop a vehicle that would dissolve in the cytoplasm after delivery. Future studies to identify effective carriers or vehicles for various kinds of target substrates are eagerly awaited.

FIG. 2. Optical delivery of a zeolite particle (marked with an arrow) doped with fura-2 into a cabbage protoplast. (a) and (b) are brightness inversion images observed by bright field microscopy, showing the process of optical delivery into the cytoplasm. (c) is the fluorescent microscopic image 1 min after delivery of the particle, where emission from intrinsic calcium ions complexed with fura-2 is observed. (d) Typical electron micrograph of a zeolite particle.

The authors thank Dr. I. Moriguchi (Department of Applied Chemistry, Faculty of Engineering, Nagasaki University) for kindly providing the zeolite.
