The origin of the lowest-temperature anomaly reported several years ago using a polycrystalline sample of the spin-ice compound Dy$_2$Ti$_2$O$_7$ has remained unresolved. Here we finally clarify its origin by susceptibility measurements down to 65 mK using single crystals under accurate control of the magnetic fields in two independent directions. We demonstrate that the transition is induced under a subtle field combination that precisely cancels the nearest-neighbor spin interactions acting on the spins on the triangular lattice within the pyrochlore structure. Contrary to the other two field-induced transitions, this transition is driven only by the interactions beyond the nearest neighbors. Our observation thus provides the first qualitative evidence for the essential importance of the dipolar interaction beyond the nearest neighbors in the spin ice.

DOI: 10.1103/PhysRevLett.95.237208

Recently, the physics of geometrically frustrated systems has attracted a great deal of attention because a variety of unconventional spin behavior emerges as a result of the suppression of ordinary long-range ordered states. Among them, the spin-ice behavior is peculiar since the spin frustration originates from ferromagnetic (FM) interactions, in contrast with frustration due to antiferromagnetic (AFM) interactions commonly found in systems based on triangular spin configuration. In spin-ice compounds such as Ho$_2$Ti$_2$O$_7$ and Dy$_2$Ti$_2$O$_7$ [1,2], crystal field effects endow the ground state of Ho$^{3+}$ and Dy$^{3+}$ ions with a doublet with strong Ising anisotropy along the local (111) direction [3]. Since these ions have large magnetic moments, the dominant interaction is FM dipolar interaction $D_{nn}$, not AFM exchange interaction $J_{nn}$, and the effective nearest-neighbor ($nn$) interaction $J_{eff} = D_{nn} + J_{nn}$ is FM. Throughout this Letter, we use the term “spin” to designate the magnetic moment of a rare earth ion. The FM-$nn$ interaction leads to the “2-in 2-out” ground state in which two of the four spins on each tetrahedron point inward and the other two outward. Such a 2-in 2-out constraint, called the ice rule from the analogy to the proton ordering in water ice, and the resulting spin configurations induce a macroscopically degenerate ground state with a residual entropy.

At first, the spin-ice behavior was expressed by the near neighbor spin-ice model considering only $J_{eff}$ [1]. However, in order to explain some key experimental features quantitatively, the dipolar spin-ice model was introduced, in which the importance of long-range dipolar interaction is emphasized [4]. By Monte Carlo simulations based on this model, it was possible to reproduce the results of powder neutron diffraction patterns [5]. The model further predicts a phase transition to the true ground state using a spin loop move algorithm [6], although the predicted transition has not been observed experimentally down to 65 mK [7]. In addition, it has recently been shown that long-range dipolar interactions are largely screened, but the remaining medium-range interaction within several neighbors plays an important role in the $q$-dependent susceptibility and is the cause of the ordering [8]. For definitive evidence of the importance of the dipolar interaction apart from the $nn$ interaction, it is crucial to demonstrate a phenomenon induced directly by the further neighbor interactions.

An outstanding problem related to the above discussion concerns the origin of the peak in the specific heat divided by temperature $C/T$ around 0.35 K observed in polycrystalline Dy$_2$Ti$_2$O$_7$ by Ramirez et al. [2]. They reported three peaks at 1.2, 0.45, and 0.35 K in $C/T$. Curiously, the peak temperatures are almost independent of the applied magnetic field strength. From the specific heat for the [110] field direction [9], the origin of the peak at 1.2 K has been ascribed to the ordering of spin chains with the Ising axes perpendicular to the field direction [10,11]. In contrast, the origin of the 0.45 K peak is most probably related to the transition from the “kagome-ice state” to the 1-in 3-out ordered state induced when the magnetic field is parallel to the [111] direction [12–15]. However, to the best of our knowledge, there have been no experimental reports clarifying the origin of the lowest-temperature peak at 0.35 K.

Very recently, Ruff et al. theoretically proposed an origin for the 0.35 K peak [11]. The pyrochlore lattice can be viewed as an alternating stacking of the triangular and kagome planes normal to the [111] direction [Fig. 1(a)]. In a range of field direction within the kagome plane centered at the [112] direction, the directions of all the spins on the kagome planes are determined by this field.
However, the spins on the triangular planes are perpendicular to this field and are experiencing no Zeeman interaction. Thus, the direction of these spins is decided only by the effective nn interaction $J_{\text{eff}}$. As shown in Fig. 1(b), three spins (1, 2, and 3) on the kagome plane are fixed in a 1-in-2-out configuration for the up tetrahedron and 2-in-1-out for the down tetrahedron. Then the ice-rule constraint makes all the spins on the triangular planes (4) point along the $[\overline{1} \overline{1} \overline{1}]$ direction. In this situation, an additional [111] magnetic field may cancel out $J_{\text{eff}}$ on spins labeled (4). These spins (4) are among themselves three nearest-neighbors on the pyrochlore lattice. Combined spins on different triangular layers form a face centered cubic lattice when effects from the spins on the kagome planes are neglected. Under such a canceling field, the residual spin-spin interactions, which consist mainly of long-range dipolar interaction and the third nearest-neighbor exchange interaction $J_3$, become important. Such interactions are expected to induce a FM ordering of these spins if $J_3$ is not too strongly AFM [11]. Here we experimentally identify the predicted field-induced transition as the origin of the anomaly at low temperature.

We used single crystals of Dy$_2$Ti$_2$O$_7$ grown by a floating zone method [7] and subsequently annealed at 700 °C in O$_2$ for 24 hours. Two samples were cut from single crystalline rods into a thin plate with the plane normal to the [111] direction and a pencil-shape rod parallel to the [111] direction. The size and mass of the two samples were approximately 1.7 × 1.7 × 0.7 mm$^3$ and 14 mg, and 0.8 × 1.0 × 3.2 mm$^3$ and 19 mg, respectively. The [112] direction lies on the (111) plane. The real component $\chi'$ and the imaginary component $\chi''$ of ac susceptibility were measured by a mutual inductance method down to 65 mK using a commercial dilution refrigerator. The strength of the ac field was 0.05 Oe-rms along the [111] direction. In order to control the magnetic field along the [112] and [111] directions independently, we used a “vector magnet” system consisting of two superconducting magnets [16]: one of the magnets points along the horizontal axis $H_z$ and the other one along the vertical axis $H_z$ (aligned to the [111] direction). We can apply fields up to 5 T for $H_z$ and 3 T for $H_x$. These two magnets are rotated around the cryostat using a pulse motor with an angular precision of 0.01°. To ensure good thermal contact, we evaporated gold films on the sample surfaces and linked the sample to the heat bath using a 100 μm gold wire. We used a pair of Hall sensors for obtaining an accurate field alignment along the [112] and [111] directions. We determine the azimuthal angle $\phi_K$ in the kagome plane between the directions of $H_x$ and [112] by the signal of Hall sensors; at $\phi_K = 0$, $H_x$ is parallel to the [112] direction. The overall accuracy of the field alignment including the resolution of the Hall sensors and misalignment between the Hall sensors and the crystal axes were within 2° for the [112] direction and 1° for the [111] direction. Because the field direction changes continuously, it is difficult to estimate an accurate demagnetization factor, and we present data here with no demagnetization correction.

In the measurements, we first applied $\mu_0 H_z = 3$ T along the [112] direction in order to hold the spins on the kagome planes and then varied an additional $H_x$ along the [111] direction. At $\mu_0 H_z = 3$ T, the Zeeman energy for the spin 1 [Fig. 1(b)] is $E_Z^{(1)} = g_J \mu_B (\mu_0 H_z) \cos \theta_1 = 19.1$ K and for the spins 2 and 3, $E_Z^{(2)} = E_Z^{(3)} = g_J \mu_B (\mu_0 H_z) \cos \theta_2 = 9.6$ K. Here $g_J$ is Landé’s $g$ factor, $J = 15/2$ is the total angular momentum, $\mu_B$ is the Bohr magneton, $\mu_0$ is permittivity, and $\theta_i$ is the angle between the field direction and Ising axis at site $i$. These values are much greater than both the effective nn interaction $J_{\text{eff}}$ = 1.11 K [4] and the measurement temperatures in this experiment. Therefore, at relatively small $H_x/H_z$, all the spins on the kagome planes are fixed by $H_z$.

In Fig. 2, we show the temperature dependence of $\chi'$ and $\chi''$ at $\mu_0 H_z = 3$ T, at various $\mu_0 H_x$, and at 497 Hz for $\phi_K = 0°$ for a pencil-shape sample. Both components are highly asymmetric with respect to $H_x$. At $\mu_0 H_x = 0.20$ T, the changes are most pronounced. In contrast, at $\mu_0 H_x = -0.20$ T and at other values of $H_x$, both components change little with temperature. Such enhancements around 0.2 T are also observed clearly in $H_x$ dependence and are discussed later (Fig. 3). In addition, even at higher temperature ($\sim 0.8$ K), both components are enhanced at $\mu_0 H_z = 0.2$ T. This large response to the small ac field strongly suggests the spins on the triangular planes are freed from the spin-ice constraint and the external fields and become paramagnetic. This is exactly expected by the theory of Ruff et al. [11] that the small [111] field ($\sim 0.24$ T) cancel out $J_{\text{eff}}$ for spins on the triangular planes.

At $\mu_0 H_z = 0.20$ T, there is a broad peak centered at 0.29 K in $\chi'$ and a peak at 0.20 K in $\chi''$. We also observed these peaks at almost the same temperature $T = 0.28 \pm 0.01$ K for different frequencies (50, 1.75 K, and 3 kHz; data not shown). This invariance of the peak temperature indicates that the peaks are associated with a transition to long-range magnetic order rather than with spin freezing.
Asymmetry in the peak field is indeed due to the predicted spin ordering on the triangular planes \[11\]. From the Ewald method \[11\], thus the scale of the critical field \(H_c\) is estimated as \(1.71\) K considering long-range dipolar interaction by the Ewald method \[11\]. Thus, the observed critical field \(H_c\) is consistent with the theoretical expectation. The expected Zeeman energy of a spin on the triangular planes by the combined \(nn\) exchange and dipolar energies is \(1.71\) K considering long-range dipolar interaction by the Ewald method \[11\].

In Fig. 4, we show the \(H_z\) dependence of \(\chi'\) and \(\chi''\) at \(\mu_0H_z = 4\) T and at \(0.30\) K for \(\phi_K = 0^\circ\) and \(180^\circ\). With decreasing horizontal field \(H_x\), the peak around \(\phi_K = 0^\circ\) appears at \(\mu_0H_x = 22\) T. This is compatible with the behavior of \(C/T\) of polycrystals reported by Ramirez et al. [2] for which the peak appears only for fields above \(1\) T. This provides additional evidence that the origin of the low temperature peak in \(C/T\) is the ordering of the spins on the triangular planes.

These anomalies in \(\chi'\) and \(\chi''\) emerge under the condition that the effective \(nn\) interactions for the triangular spins are canceled out and the long-range dipolar and further neighbor exchange interactions between these spins are important. Until now, there have been some discussions about the importance of the long-range interactions for explaining the physics of spin ice, for example, fitting the specific heat \(C_v\) \[4,5\] and the neutron structure factor \(S(q)\) \[5\]. In these discussions, while of qualitative relevance, the importance of the long-range interaction was not made so qualitatively clear and important. Our report here marks the first experimental demonstration of a phenomenon in the spin ice originating from the long-range interaction.

The observed critical field is in good agreement with the theoretical expectation. The predicted process also explains the behavior in polycrystals: Grains satisfying the critical condition \(\mu_0H_{[111]} = \mu_0H_z = 0.25\) T with
resolved anomaly reported in the polycrystals. We clarified its origin as a field-induced magnetic transition governed by the long-range dipolar interaction beyond the nearest neighbors, as predicted by the recent theory by Ruff et al.  

The authors are grateful to M. Gingras, J. Ruff, and R. Melko for useful discussion and sending their results on the theoretical expectation before publication, to K. Deguchi for his technical help as well as useful advice, and to H. Fukazawa and S. Nakatsuji for useful discussion.
