Microstructures were fabricated by a photothermal process in a low-melting organic-inorganic hybrid material of tin silicophosphate doped with Nd3+ ion as a light absorber. The negative refractive index change of the order of 10⁻³ was photothermally induced inside the low-melting glass with a spatial resolution ranging from 10 to 100 μm using a 514.5 nm emission from an Ar⁺ laser of less than 30 mW as the excitation source. The volume expansion due to the photogenerated heat at the laser focus is found to be responsible for the photothermally induced negative photorefractive index change. © 2006 American Institute of Physics. Transparent materials with a periodic modulation of the refractive index can be used for two-dimensional (2D) or three-dimensional (3D) photonic devices that control the light wave for optical information processing. Many techniques to fabricate microstructures including photolithography, focused ion beam, lithography, electroplating, and molding, etc., have been practically utilized to make such devices. The femtosecond laser fabrication of transparent materials through multiphoton absorption is also attractive for producing microstructures. The laser direct writing technique using ultraviolet laser sources is a facile way to make relatively simple telecommunication devices. recently, the photoinduced thermal fabrication of a micro/nanostructure has been reported by several groups. The photoinduced crystallization of nonconventional metal oxide glasses was reported to fabricate microstructures made of nonlinear optical crystals. The formation of a nanostructure involving the laser induced expansion of the material has also been reported. The laser welding technique of thermoplastic polymers was achieved by a laser melting setup for the laser fabrication. A collimated beam was focused on the interior of the material to be fabricated using a 20× objective lens [f=9 mm, numerical aperture (NA) =0.3 or f=2 mm, (NA)=0.4]. The modified region was directly observed by an optical microscope after the irradiation. The photoinduced refractive index change was estimated by in situ Mach-Zehnder interferometry (MZI).

Preparation of the tin(II) methyl-modified silicophosphate glasses was reported elsewhere. The resultant molten glass was poured into a Pyrex cuvette in order to obtain an optically smooth surface for laser irradiation. The glass transition temperature of the hybrid glass was estimated to be 26 °C. The coefficients of thermal expansion were estimated to be 4×10⁻⁴ and 2×10⁻⁵ K⁻¹ above and below the glass transition temperature, respectively. An Ar⁺ laser of 514.5 nm radiation (Spectra Physics Co., USA) was used as the excitation source. Figure 1(a) shows the present optical setup for the laser fabrication. A collimated beam was focused on the interior of the material to be fabricated using a 20× objective lens [f=9 mm, numerical aperture (NA) =0.3 or f=2 mm, (NA)=0.4]. The modified region was directly observed by an optical microscope after the irradiation. The photoinduced refractive index change was estimated by in situ and ex situ MZI. Figure 1(b) shows the

Me₂SiCl₂·SnCl₂·H₃PO₄·NdCl₃·6H₂O=0.75:1:1:0.02. The glass was doped with rare earth ion, Nd³⁺ ion (0.7% in cationic ratio), as a light absorber. Laser fabrication was carried out using an Ar⁺ laser in the cw operation mode of which the light intensity was less than 30 mW. The writing dynamics was investigated by in situ Mach-Zehnder interferometry (MZI).
optical setup of the \textit{in situ} MZI. He–Ne laser (632.8 nm) was used as the probe light source. The objective light was focused on the irradiated region by a convex lens ($f=50$) to observe the refractive index change. In a case of the \textit{ex situ} MZI, the writing beam was turned off. A circular fringe pattern was observed in order to determine the sign of the refractive index change in terms of the direction of the fringe ring movement.

Figure 2 shows the optical absorption spectra of the doped and undoped glasses. Several sharp absorption bands corresponding to the Nd$^{3+}$ $f$-$f$ transitions are seen in the spectrum of the doped glass. When the doped glass was excited at 514.5 nm, the photoluminescence band is observed at 536 nm. The excitation energy is emitted to the surroundings. The thinner line, with a di-

Assuming that the region subjected to the refractive index change is uniform and cylindrical in shape with a diameter of around 70 $\mu$m (picture is shown later), the phase shift can be converted into the refractive index change. The estimated refractive index change under laser irradiation (10 mW) at the saturated phase shift is $\sim0.05$. It is well known that the thermo-optic coefficient is expressed as

$$dn/dT = (n^2-1)(n^2+1)/(6n)(\phi-\beta),$$

where $\phi$ is the temperature coefficient of the electron polarizability and $\beta$ is the thermal expansion coefficient. For the organic-inorganic hybrid siloxane materials, $dn/dT$ largely depends on $\beta$ rather than $\phi$ because the former is much larger than the latter.\textsuperscript{16} The refractive index change $\Delta n$ and $\beta$ can be correlated by the Lorentz-Lorenz (LL) relationship

$$\Delta n = -\frac{(n^2+2)(n^2-1)}{6n} \left[1 - \frac{V\Delta R}{R\Delta V}\right] \Delta V/V,$$

where $R$ is the molar refraction, $V$ the molar volume, and $(\Delta V/\Delta T)/V=3(\Delta L/\Delta T)/L=3\beta$. Therefore, volume change of $\sim3.8\%$ results in the refractive index change of 0.05. We can then estimate the temperature change at the laser focus. For example, the temperature rises to be around 100 $^\circ$C under steady state irradiation of 10 mW laser through a micro-objective of $f=9$ mm, NA=0.3.

As shown in Fig. 4, line, dot, phase gratings, and an array of voids in the micrometer range could be fabricated inside the glasses. The former two kinds of structures were written at a laser power of 20 mW. It took 20 and 15 min to fabricate line and dot, respectively. Although the diameter of the laser beam waist is estimated to be around 5 $\mu$m, that of the written line was around 70 $\mu$m as shown in Fig. 4. This broadening is explained by the thermal diffusion from the laser focus to the surroundings. The thinner line, with a diameter of around 10 $\mu$m, could be fabricated using a higher NA micro-objective ($f=2$ mm, NA=0.4, laser power: 10 mW). The phase gratings can also be fabricated inside the glass as shown in Fig. 4(c). The amplitude of the refractive index modulation was estimated as $3 \times 10^{-3}$ by assuming the Raman-Nas-type grating.\textsuperscript{17} On increasing the laser power (>40 mW), an array of voids could be made inside the
glasses. By applying an electric field during the laser irradiation, it was possible to induce the optically anisotropic structures in the present glass. The induced refractive index changes could be erased by the post-heat-treatment above ~50 °C and rewritten by the subsequent laser irradiation.

The fabricated structures [Fig. 4(a)] remained unchanged for more than several months. The refractive index change by the laser irradiation was estimated by ex situ MZI. Figure 5 shows the cross-sectional distribution of the phase shift of the line shown in Fig. 4, which was estimated by scanning the line structure across the focused probe beam of the MZI. The sign of the refractive index change was estimated by the laser irradiation was estimated by

$$\text{Phase shift} / 2\pi$$

Displacement / μm

expansion of the glass at the laser focus, and hence the densification occurred at the periphery of the heated region, which is depicted in Fig. 5(b). Consequently, we can say that a persistent photorefractive index change could be induced by irradiating a low-power density cw laser light at a wavelength that should be well matched with the optical absorption band of the doped light absorbers.

In conclusion, we can fabricate microstructures inside low-melting transparent media doped with light absorbers by a photothermal process. Several microstructures of which the size was in the micrometer range from 10 to 100 μm were fabricated using a cw Ar⁺ laser (<30 mW) as the excitation source. The negative refractive index change could be induced by the thermal expansion of the irradiated part, and consequently, a positive index change was observed at its periphery. The obtained structure remained unchanged for several months under ambient conditions. The present photothermal fabrication technique for low-melting media could be applicable for low-melting glasses, thermoplastic polymers, etc. It was also confirmed by the present authors that an organic dye would also be useful as light absorbers. Such a lower energy fabrication seems quite environmentally friendly.
