High energy neutrino emission from gamma-ray bursts (GRBs) is discussed. In this paper, by using the simulation kit GEANT4, we calculate proton cooling efficiency including pion-multiplicity and proton-inelasticity in photomeson production. First, we estimate the maximum energy of accelerated protons in GRBs. Using the obtained results, neutrino flux from one burst and a diffuse neutrino background are evaluated quantitatively. We also take account of cooling processes of pion and muon, which are crucial for resulting neutrino spectra. We confirm the validity of analytic approximate treatments on GRB fiducial parameter sets, but also find that the effects of multiplicity and high-inelasticity can be important on both proton cooling and resulting spectra in some cases. Finally, assuming that the GRB rate traces the star formation rate, we obtain a diffuse neutrino background spectrum from GRBs for specific parameter sets. We introduce the nonthermal baryon-loading factor, rather than assume that GRBs are main sources of ultra-high energy cosmic rays (UHECRs). We find that the obtained neutrino background can be comparable with the prediction of Waxman and Bahcall, although our ground in estimation is different from theirs. In this paper, we study on various parameters since there are many parameters in the model. The detection of high energy neutrinos from GRBs will be one of the strong evidences that protons are accelerated to very high energy in GRBs. Furthermore, the observations of a neutrino background has a possibility not only to test the internal shock model of GRBs but also to give us information about parameters in the model and whether GRBs are sources of UHECRs or not.

I. INTRODUCTION

Gamma-ray bursts (GRBs) are the most powerful explosions in the universe. The observed isotropic energy can be estimated to be larger than 10^{52} ergs [1,2]. The high luminosity and the rapid time variability lead to the compactness problem. This problem and the hardness of observed photon spectra imply that γ -ray emission should be results of dissipation of kinetic energy of relativistic expanding shells. In the standard model of GRBs, such a dissipation is caused by internal shocks—internal collisions among the shells (see reviews e.g., [3–5]). Internal shock scenario requires a strong magnetic field, typically 10^4 – 10^7 G, which can accelerate electrons to high energy enough to explain observed γ -ray spectra by synchrotron radiation. Usually, Fermi acceleration mechanism is assumed to be working not only for electrons but also for protons, which can be accelerated up to a high energy within the fiducial GRB parameters. Physical conditions allow protons accelerated to greater than 10^{20} eV and energetics can explain the observed flux of ultra-high energy cosmic rays (UHECRs), assuming that similar energy goes into acceleration of electrons and protons in the shell [6–9]. Such protons accelerated to the ultra-high energy cannot avoid interacting with GRB photons. This photomeson production process can generate very high energy neutrinos and gamma rays [10]. Whether GRBs

are sources of UHECRs or not, internal shock models predict the flux of very high energy neutrinos at the Earth [11–13]. Many authors have investigated neutrino emission from GRBs. Ice Čerenkov detectors such as AMANDA at the South Pole have already been constructed and are taking data [14–16]. Now, the future 1 km³ detector, IceCube is being constructed [17–19]. In the Mediterranean Sea, ANTARES and NESTOR are under construction [20]. If the prediction is correct, these detectors may detect these neutrinos correlated with GRBs in the near future.

In this paper, we execute the Monte Carlo simulation kit GEANT4 [21] and simulate the photomeson production that causes proton energy loss. As a result, we can get meson spectrum and resulting neutrino spectrum from GRBs quantitatively. In our calculation, we take into account pion-multiplicity and proton-inelasticity, which are often neglected or approximated analytically in previous works, although they may be important in some cases [22,23]. We also take into account the synchrotron loss of mesons and protons. These cooling processes play a crucial role for the resulting neutrino spectrum. Our models and method of calculation are explained in Sec. II. One of our purposes is to seek physical conditions allowing proton to be accelerated up to ultra-high energy. Similar calculations are carried by Asano [13], in which the possibility that a nucleon creates pions multiple times in the dynamical time scale is included but multiplicity is neglected. Using obtained results, we also investigate efficiency of neutrino emission for various parameter sets.

Since there are many model uncertainties in GRBs, such a parameter survey is meaningful. Our final goal is to calculate a diffuse neutrino background from GRBs for specific parameter sets. A unified model for UHECRs from GRBs is very attractive [6,7,10], although it requires GRBs being strongly baryon-loaded [24]. Even if observed UHECRs are not produced mainly by GRBs, high energy neutrino emission from GRBs can be expected. Hence, we leave the nonthermal baryon-loading factor as a parameter. In this paper, assuming GRBs trace star formation rate, we calculate a neutrino background from GRBs and compare our results with the flux obtained by Waxman and Bahcall [8]. The design characters of neutrino detectors are being determined in part by the best available theoretical models, so numerical investigation of high energy neutrino fluxes should be important. Finally, we will consider the implications of neutrino observations and discuss a possibility that neutrino observation gives some information on the nonthermal baryon-loading factor and the inner engine, if the internal shock model is true. Our numerical results are shown in Sec. III. Our summary and discussions are described in Sec. IV.

II. METHOD OF CALCULATION

A. Physical conditions

Throughout this paper, we consider the epoch that internal shocks occurs (see reviews e.g., [3–5]). We focus on long GRBs, whose duration is typically ~ 30 s and they are likely to be related with the deaths of short-lived massive stars (see Sec. II E). The internal shock model can produce the observed highly variable temporal profiles [25,26]. In this model, the radial time scale is comparable with the angular time scale (see e.g., [3]), and each time scale is related to the pulse width. Widths of individual pulses vary in a wide range. GRB pulses with ~ 0.1 – 10 s durations and separations for bright long bursts are typical ones [27,28]. The shortest spikes have millisecond or even submillisecond widths in some bursts. It will reflect the intermittent nature of the fireball central engine. The internal collision radii are determined by the separation of the subshells, which is written by d in the comoving frame. Since the observed pulse width is given by $\delta t \approx d/2\Gamma c$, the internal collision radius is expressed by the commonly used relation, $r \approx 2\Gamma^2 c \delta t \approx 6 \times 10^{14} (\Gamma/300)^2 (\delta t/0.1 \text{ s}) \text{ cm}$, where Γ is a bulk Lorentz factor of the shell, which is larger than 100. We consider collision radii in the range of $(10^{13}$ – $10^{16})$ cm in our calculation. The width of the subshells is constrained by the observed variability time and the duration, and it is typically written by $l \approx r/\Gamma$, where r is the radius at which internal shocks begin to occur. In this paper, we leave l as a parameter because the precise width of each subshell is unknown. The dynamical time of each collision is $t_{\text{dyn}} \approx l/c$. For simplicity, we assume each collision radiates similar energy, $E_{\gamma}^{\text{iso}} = E_{\gamma,\text{tot}}^{\text{iso}}/N$, where

N is the number of collisions and it is almost the number of subshells [25]. Although we do not know about N precisely, we set $N \sim (10$ – $100)$ in our calculation since the number of pulses per bright long burst is typically the order of dozens [29]. The geometrically corrected GRB radiation energy is typically $E_{\gamma,\text{tot}} = 1.24 \times 10^{51} h_{70}^{-1} \text{ ergs}$ [1,2], and we fix $E_{\gamma,\text{tot}}$ throughout this paper. The isotropic energy is a few orders of magnitude larger than this energy, and we take $E_{\gamma,\text{tot}}^{\text{iso}} = f_b^{-1} E_{\gamma,\text{tot}} \sim (10^{52}$ – $10^{54}) \text{ ergs}$. Here, $f_b \equiv \theta_j^2/2$ is a beaming factor of GRB jet. In the prompt phase $1/\Gamma \lesssim \theta_j$ has to be satisfied. Once we determine E_{γ} and N , f_b is also determined.

The photon energy density in the comoving frame is given by,

$$U_{\gamma} = \frac{E_{\gamma}^{\text{iso}}}{4\pi\Gamma r^2 l} \beta. \quad (1)$$

In the standard model, the prompt spectrum is explained by the synchrotron radiation from electrons. For simplicity, we assume that the GRB photon spectrum obeys a power-law spectrum. That is,

$$\frac{dn}{d\varepsilon} \propto \begin{cases} \varepsilon^{-\alpha} & (\text{for } \varepsilon^{\text{min}} < \varepsilon < \varepsilon^b) \\ \varepsilon^{-\beta} & (\text{for } \varepsilon^b < \varepsilon < \varepsilon^{\text{max}}) \end{cases}. \quad (2)$$

The observed break energy is ~ 250 keV, which corresponds to the break energy in the comoving frame, $\varepsilon^b \sim$ a few keV. So we set ε^b to 1 keV for $E_{\gamma}^{\text{iso}} = 2 \times 10^{51} \text{ ergs}$, 3 keV for $E_{\gamma}^{\text{iso}} = 2 \times 10^{52} \text{ ergs}$, 6 keV for $E_{\gamma}^{\text{iso}} = 2 \times 10^{53} \text{ ergs}$. In addition, we set spectral indices to $\alpha = 1$, $\beta = 2.2$ as fiducial values and $\alpha = 0.5$, $\beta = 1.5$ as a flatter case. We take the minimum energy as 1 eV and the maximum energy as 10 MeV. Below 1 eV, the synchrotron self-absorption will be crucial, while above 10 MeV, the pair creation will be important [30]. To explain the observed emission, the internal shock model requires the strong magnetic energy density, which is expressed by $U_B = \epsilon_B U_{\gamma}$. We take $\epsilon_B = 0.1, 1, 10$ as a parameter.

B. Acceleration and cooling of proton

The radiating particles are considered to gain their energies by stochastic acceleration. The most promising acceleration process is Fermi acceleration mechanism. We assume that electrons and protons will be accelerated in GRBs by first order Fermi acceleration by diffusive scattering of particles across strong shock waves. The acceleration time scale is given by $t_{\text{acc}} \approx (3cr_L/\beta_A^2)(B/\delta B)^2$, where r_L is Larmor radius of the particle, $\beta_A = v_A/c$, v_A is Alfvén velocity, and δB is the strength of the turbulence in the magnetic field [31,32]. Assuming that the diffusion coefficient is proportional to the Bohm diffusion coefficient, we can write the acceleration time of proton as follows,

$$t_{\text{acc}} \equiv \eta \frac{r_L}{c} = \eta \frac{\varepsilon_p}{eBc}. \quad (3)$$

In usual cases $\eta \gtrsim 10$ would be more realistic, and $\eta \sim 1$ will give a reasonable lower limit for any kind of Fermi acceleration time scale. As for the ultrarelativistic shock acceleration, the acceleration time scale can be written $t_{\text{acc}} \sim \varepsilon_p / \sqrt{2} \Gamma_{\text{rel}} e B c$, where Γ_{rel} is the relative Lorentz factor of the upstream relative to the downstream [33]. For the case of mildly relativistic shocks, $\eta \sim 1$ is probably possible [34]. Hence, we set $\eta = 1$ optimistically in our calculation. Corresponding to $t_{\text{acc}} < t_{\text{dyn}}$, proton energy is restricted by $\varepsilon_p \lesssim e B l / \eta$, which satisfies the requirement that proton's Larmor radius has to be smaller than the size of the acceleration sites. Even when GRBs are jetlike, the transverse size will be larger than the radial size r / Γ because the jet opening angle θ_j is larger than $1 / \Gamma$, so $t_{\text{acc}} < t_{\text{dyn}}$ holds. Proton's maximal energy is also constrained by various cooling processes, for example, proton synchrotron cooling, inverse Compton (IC) cooling, and photohadronic cooling and so on. First, the synchrotron loss time scale for relativistic protons is,

$$t_{\text{syn}} = \frac{3m_p^4 c^3}{4\sigma_T m_e^2} \frac{1}{\varepsilon_p} \frac{1}{U_B}. \quad (4)$$

Second, we have to consider IC cooling, but we ignore IC process in this paper for simplicity. This contribution is considered to be small in the region where proton energy is above around 10^{17} eV [13]. Although IC will be more important than synchrotron loss when proton energy is below that energy, we can ignore this fact because photohadronic loss will dominate IC for our parameters. Furthermore, in our cases IC does not matter for the purpose to determine the proton maximum energy. Third, the photohadronic cooling process is important, and pions and resulting neutrinos appear through pion decays. When the internal shock occurs at small radii, photohadronic cooling may dominate synchrotron cooling. We will discuss this process in the next subsection. Finally, we take into account the adiabatic cooling process, which has a time scale t_{ad} independent of the proton energy, and direct ejection of protons from the emission region. The latter may be dependent on the proton energy if diffusive losses are relevant. For simplicity, we neglect diffusive losses and assume that protons are confined over the time scale set by adiabatic expansion. From above, the total proton loss time scale is expressed as follows,

$$t_p^{-1} \equiv t_{p\gamma}^{-1} + t_{\text{syn}}^{-1} + t_{\text{ad}}^{-1} \leq t_{\text{acc}}^{-1}. \quad (5)$$

The maximum energy of proton is determined by this inequality, but we do not know the minimum energy. We set the minimum energy of proton to 10 GeV. Proton energy density can be expressed by $U_p = \epsilon_{\text{acc}} U_\gamma$, where ϵ_{acc} is a nonthermal baryon-loading factor. However, we have few knowledge about how many protons can be accelerated for now. So, we adopt $\epsilon_{\text{acc}} = 10$ as a fiducial parameter, assuming that a significant fraction of relativistic protons can be accelerated. It is also assumed that

proton distribution has $dn_p/d\varepsilon_p \propto \varepsilon_p^{-2}$ according to first order Fermi acceleration mechanism.

C. Photomeson production

GRB photons produced by synchrotron radiation and relativistic protons accelerated in the internal shocks can make mesons such as $\pi^\pm$ and $K^\pm$, and secondary electrons, positrons, gamma rays, and neutrinos through the photomeson production process. Some authors used Δ -approximation for simplicity, but this approximation underestimates proton energy loss in the high energy region. This is because the theoretical model predicts the increase of cross section in the high energy regions. We use the Monte Carlo simulation toolkit GEANT4 [21], which includes cross sections up to 40 TeV [35]. Above 40 TeV, we extrapolate cross sections up to the maximum energy, which is around 10 PeV. We checked the accuracy of GEANT4 photomeson cross section within a few percent, comparing with PDG data [36]. Moreover, we take into account inelasticity. Around the Δ -resonance, inelasticity is about 0.2. But above the resonance, inelasticity increases with energy, and the value is about 0.5–0.7, that is consistent with Mücke *et al.* [22]. However, it seems that the current version of GEANT4 tends to overestimate the amount of produced neutral pions, leading to underestimation of the amount of charged pions by a factor of ~ 3 . So we approximate $\pi^+ : \pi^0 = 1 : 1$ for single-pion production, and $\pi^+ \pi^- : \pi^+ \pi^0 = 7 : 4$ for double-pion production [32,37]. Photomeson cooling time scale of relativistic protons is given by the following equation for isotropic photon distribution [10].

$$t_{p\gamma}^{-1}(\varepsilon_p) = \frac{c}{2\gamma_p^2} \int_{\bar{\varepsilon}_{th}}^{\infty} d\bar{\varepsilon} \sigma_{p\gamma}(\bar{\varepsilon}) \kappa_p(\bar{\varepsilon}) \bar{\varepsilon} \int_{\bar{\varepsilon}/2\gamma_p}^{\infty} d\varepsilon \varepsilon^{-2} \frac{dn}{d\varepsilon}, \quad (6)$$

where $\bar{\varepsilon}$ is the photon energy in the rest frame of proton, γ_p is the proton's Lorentz factor, κ_p is the inelasticity of proton, and $\bar{\varepsilon}_{th}$ is the threshold photon energy for photomeson production in the rest frame of the incident proton, which is $\bar{\varepsilon}_{th} \approx 145$ MeV. Using this equation, we can obtain photomeson production efficiency. Protons with 1 PeV energy will effectively interact with soft X-ray photons with energy $\gtrsim 0.16$ keV. Pion spectrum can be obtained by executing GEANT4 through the following equation,

$$\begin{aligned} \frac{dn_\pi}{d\varepsilon_\pi} &= \int_{\varepsilon_p^{\min}}^{\varepsilon_p^{\max}} d\varepsilon_p \frac{dn_p}{d\varepsilon_p} \int_{\varepsilon^{\min}}^{\varepsilon^{\max}} d\varepsilon \frac{dn}{d\varepsilon} \int \frac{d\Omega}{4\pi} \\ &\times \frac{d\sigma_{p\gamma}(\varepsilon, \Omega, \varepsilon_p) \xi}{d\varepsilon_\pi} c t_p, \end{aligned} \quad (7)$$

where $dn_p/d\varepsilon_p$ and $dn/d\varepsilon$ is proton and photon distribution in the comoving frame, ξ is the pion-multiplicity, and t_p is the proton loss time scale, which is defined by the Eq. (5).

D. Neutrinos from pion and muon decay

By using GEANT4, we can get pion spectra. Hence, neutrino spectra follow from the spectra of pions and muons. Neutrinos are produced by the decay of $\pi^\pm \rightarrow \mu^\pm + \nu_\mu(\bar{\nu}_\mu) \rightarrow e^\pm + \nu_e(\bar{\nu}_e) + \nu_\mu + \bar{\nu}_\mu$. The life times of pions and muons are $t_\pi = \gamma_\pi \tau_\pi$ and $t_\mu = \gamma_\mu \tau_\mu$ respectively. Here, $\tau_\pi = 2.6033 \times 10^{-8}$ s and $\tau_\mu = 2.1970 \times 10^{-6}$ s are the mean life times of each particle. When pions decay with the spectrum, $dn_\pi/d\varepsilon_\pi$ by $\pi^\pm \rightarrow \mu^\pm + \nu_\mu(\bar{\nu}_\mu)$, the spectrum of neutrinos are given by [38],

$$\frac{dn_\nu}{d\varepsilon_\nu} = \frac{m_\pi c}{2\varepsilon_\nu^*} \int_{\varepsilon_\pi^{\min}}^{\infty} d\varepsilon_\pi \frac{1}{p_\pi} \frac{dn_\pi}{d\varepsilon_\pi}. \quad (8)$$

Here, $\varepsilon_\nu^* = (m_\pi^2 - m_\mu^2)c^2/2m_\pi$ and $\varepsilon_\pi^{\min} = (\varepsilon_\nu^*/\varepsilon_\nu + \varepsilon_\nu/\varepsilon_\nu^*)/2$. Similarly, we can get muon spectrum from pion spectrum. Muon decay is the three-body-decay process, which is slightly more complicated than the case of two-body-decay. Given the spectrum of muon, it can be calculated by the following equation [39],

$$\begin{aligned} \frac{dn_\nu}{d\varepsilon_\nu} = & \int_{m_\mu c^2}^{\infty} d\varepsilon_\mu \frac{1}{c p_\mu} \frac{dn_\mu}{d\varepsilon_\mu} \int_{\varepsilon_{\mu 1}^*}^{\varepsilon_{\mu 2}^*} d\varepsilon_\nu^* \frac{1}{\varepsilon_\nu^*} \\ & \times (f_0(\varepsilon_\nu^*) + \cos\theta_\nu^* f_1(\varepsilon_\nu^*)), \end{aligned} \quad (9)$$

where $\varepsilon_{\mu 1}^* = \gamma_\mu \varepsilon_\nu - (\gamma_\mu^2 - 1)^{1/2} \varepsilon_\nu$, $\varepsilon_{\mu 2}^* = \min(\gamma_\mu \varepsilon_\nu + (\gamma_\mu^2 - 1)^{1/2} \varepsilon_\nu, (m_\mu^2 - m_e^2)c^2/2m_\mu)$, and ε_ν^* is the energy of muon-neutrino in the muon-rest frame. $f_0(x)$ and $f_1(x)$ can be calculated by the quantum field theory, which are, $f_0(x) = 2x^2(3 - 2x)$, $f_1(x) = 2x^2(1 - 2x)$, and $x = 2\varepsilon_\nu^*/m_\mu c^2$. However, because of cooling processes of $\pi^\pm$ and $\mu^\pm$, these equations have to be applied at each time step. The pion or muon decay probability is $(1 - \exp(-\Delta t/t_{\pi,\mu}))$, and meanwhile cooled by synchrotron cooling and adiabatic cooling. The synchrotron radiating time scale is given by replacing proton mass with pion or muon mass in the Eq. (4). The adiabatic cooling time scale is still comparable to dynamical time scale. We neglect IC process of pions and muons in our calculation, because Klein-Nishina suppression will work in our cases [13]. We also neglect neutrinos due to neutron decay $n \rightarrow p + e^- + \bar{\nu}_e$, whose time scale is much larger than the dynamical time scale t_{dyn} .

Roughly speaking, in the Δ -resonance picture, neutrino spectrum follows proton spectrum above the break energy which is given by, $\varepsilon_p^b \varepsilon^b \sim 0.3$ GeV, and becomes harder below the break by $\varepsilon_p^{\beta-1}$ due to $f_{p\gamma} \equiv t_{\text{dyn}}/t_{p\gamma} \propto \varepsilon_p^{\beta-1}$ [10]. In addition, if $t_{\pi,\mu} > t_{\text{ad}}$, neutrino spectrum will be suppressed by $t_{\text{ad}}/t_{\pi,\mu}$ due to adiabatic cooling. If $t_{\pi,\mu} > t_{\text{syn}}$, neutrino spectrum will be suppressed by $t_{\text{syn}}/t_{\pi,\mu}$ due to synchrotron cooling. These statements will be confirmed numerically by above methods.

E. GRB diffuse neutrino background

UHECRs may come from GRBs [6,7]. This hypothesis requires that the conversion of the initial energy of a fireball into UHECRs must be very efficient. In other words, this needs a very large value of ϵ_{acc} . On the other hand, Waxman and Bahcall [8] have derived a model independent upper bound for high energy neutrino background from sources optically thin to photomeson production. This bound is conservative and robust [9] and it is called as the Waxman and Bahcall limit (WB limit). They have also estimated the contribution of GRBs to the high energy neutrino background, assuming that UHECRs come from GRBs, and showed this contribution is consistently below the WB limit. Whether UHECRs come from GRBs or not, numerical calculations on neutrino spectrum obtained by our method shown above can provide a diffuse neutrino background quantitatively, assuming the GRB rate follows some distribution. The demonstration that long-duration GRBs are associated with core-collapse supernovae [40] implies that GRB traces the deaths of short-lived massive stars. Furthermore, GRBs can be detected to very high redshifts, unhindered by intervening dust and the current record is recently observed GRB 050904 [41]. This holds the promise of being useful tracers of star formation rate (SFR) in the universe [42–44]. However, there remain many problems such as observational bias and the effect of dust-enshrouded infrared starbursts, although these are crucial for to which extend GRBs follow the SFR and to which extend they can be used to determine the SFR at high redshifts.

In this paper, we estimate neutrino background for several models, following Nagataki *et al.* [45,46]. First, we adopt the hypothesis that GRB rate traces the SFR, $R_{\text{GRB}} \propto R_{\text{SF}}$. This ansatz that GRBs are likely to trace the observed SFR in a globally averaged sense, is not precluded for now although there are some uncertainties as described above. Second, we use parameterization of Porciani and Madau [47], especially employing their models SF1, SF2 and SF3, which are expressed by following equation in a flat Friedmann-Robertson-Walker universe,

$$\begin{aligned} \psi_*^{\text{SF1}}(z) = & 0.32 f_* h_{70} \frac{\exp(3.4z)}{\exp(3.8z) + 45} \\ & \times F(z, \Omega_m, \Omega_\Lambda) M_\odot \text{ yr}^{-1} \text{ Mpc}^{-3} \end{aligned} \quad (10a)$$

$$\begin{aligned} \psi_*^{\text{SF2}}(z) = & 0.16 f_* h_{70} \frac{\exp(3.4z)}{\exp(3.4z) + 22} \\ & \times F(z, \Omega_m, \Omega_\Lambda) M_\odot \text{ yr}^{-1} \text{ Mpc}^{-3} \end{aligned} \quad (10b)$$

$$\begin{aligned} \psi_*^{\text{SF3}}(z) = & 0.21 f_* h_{70} \frac{\exp(3.05z - 0.4)}{\exp(2.93z) + 15} \\ & \times F(z, \Omega_m, \Omega_\Lambda) M_\odot \text{ yr}^{-1} \text{ Mpc}^{-3}, \end{aligned} \quad (10c)$$

where $F(z, \Omega_m, \Omega_\Lambda) = (\Omega_m(1+z)^3 + \Omega_\Lambda)^{1/2}/(1+z)^{3/2}$, $h_{70} = H_0/70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, and we adopt the standard Λ CDM cosmology ($\Omega_m = 0.3$, $\Omega_\Lambda = 0.7$). The correction

factor f_* is introduced for uncertainties of SFR. We set $f_* = 1$, which is consistent with mildly dust-corrected UV data at low redshift; on the other hand, it may underestimate the results of other wave band observations and we only have to correct f_* in such cases [48]. Many works have modeled the expected evolution of the cosmic SFR with redshift, but there are some uncertainties (in particular at high redshift $z \gtrsim 6$). In addition, even observational estimates at modest high redshift have been plagued by uncertainties arising from a result of correction for dust extinction. Because of a few constraints at high redshift, we cannot avoid extrapolating SFRs. For these reasons, we employ three models.

The inner engine of GRBs is still unknown, although there are several plausible candidates. One of the plausible models of GRB progenitors is a collapsar model [49], because GRBs likely have a link with the explosion of a massive ($M \gtrsim (35 - 40)M_\odot$) rotating star whose core collapses to form a black hole [49–51]. Assuming that massive stars with masses larger than $\sim 35M_\odot$ explode as GRBs, GRB rate can be estimated for a selected SFR by multiplying the coefficient,

$$f_{cl} \times \frac{\int_{35}^{125} dm \phi(m)}{\int_{0.4}^{125} dmm \phi(m)} = 1.5 \times 10^{-3} f_{cl} M_\odot^{-1}, \quad (11)$$

where $\phi(m)$ is the initial mass function (IMF) and mass is the stellar mass in solar units. Here we adopt the Salpeter's IMF ($\phi(m) \propto m^{-2.35}$), assuming that the IMF does not change with time, which may be a good approximation if there are no significant correlations between the IMF and the environment in which stars are born. For now, extant evidences seem to argue against such correlations at $z \lesssim 2$, although this validity at high redshift is uncertain [52]. For comparison, we can obtain $R_{SN}(z) = 0.0122 M_\odot^{-1} \psi_*^{\text{SF}}(z)$ assuming that all stars with $M > 8M_\odot$ explode as core-collapse supernovae. This result combined with $f_* = 1$ agrees with the observed value of local supernova rate, $R_{SN}(0) = (1.2 \pm 0.4) \times 10^{-4} h_{70}^3 \text{ yr}^{-1} \text{ Mpc}^{-3}$ [53]. In the Eq. (11), we introduce an unknown parameter, f_{cl} , which expresses the fraction of the collapsars whose mass range is in $(35-125)M_\odot$ are accompanied with GRBs. We normalize f_{cl} using the value of GRB rate, $R_{GRB}(0) = 17 h_{70}^3 \text{ yr}^{-1} \text{ Gpc}^{-3}$, obtained by recent analysis using BATSE peak flux distribution [54,55]. From Eqs. (10a)–(10c), combined with (11), we obtain following expressions in units of $\text{yr}^{-1} \text{ Gpc}^{-3}$,

$$R_{GRB1}(z) = 17 \left(\frac{f_{cl}}{1.6 \times 10^{-3}} \right) \frac{46 \exp(3.4z)}{\exp(3.8z) + 45} \quad (12a)$$

$$R_{GRB2}(z) = 17 \left(\frac{f_{cl}}{1.6 \times 10^{-3}} \right) \frac{23 \exp(3.4z)}{\exp(3.4z) + 22} \quad (12b)$$

$$R_{GRB3}(z) = 21 \left(\frac{f_{cl}}{1.6 \times 10^{-3}} \right) \frac{24 \exp(3.05z - 0.4)}{\exp(2.93z) + 15}. \quad (12c)$$

We also consider the Rowan-Robinson SFR [56] that can

be fitted with the expression in units of $\text{yr}^{-1} \text{ Gpc}^{-3}$,

$$R_{RR}(z) = 41 \left(\frac{f_{cl}}{1.6 \times 10^{-3}} \right) \begin{cases} 10^{0.75z} & (\text{for } z < 1) \\ 10^{0.75} & (\text{for } z > 1) \end{cases} \quad (13)$$

The parameter, f_{cl} is unknown for now, but $\sim 2 \times 10^{-3}$ will give the reasonable upper limit for the probability for one collapsar to generate a GRB, which corresponds to the value if all the GRBs come from collapsars. On the other hand, direct estimates from the sample of GRBs with determined redshifts are contaminated by observational biases and are insufficient to determine the precise rate and luminosity function. In addition, the observed peak luminosity also depends on intrinsic spectrum. More precise data on GRBs will give us information on the accurate GRB rate. For these reasons, we leave the value of f_{cl} as a parameter here.

In order to get the differential number flux of background neutrinos, first we compute the present number density of the background neutrinos per unit energy from GRBs. The contribution of neutrinos emitted in the interval of the redshift $z \sim z + dz$ is given as,

$$dn_\nu^{\text{ob}}(E_\nu) = R_{GRB}(z)(1+z)^3 \frac{dt}{dz} \frac{dN_\nu(E'_\nu)}{dE'_\nu} dE'_\nu (1+z)^{-3}, \quad (14)$$

where $E'_\nu = (1+z)E_\nu$ is the energy of neutrinos at redshift z , which is now observed as E_ν and $dN_\nu(E'_\nu)/dE'_\nu$ is the number spectrum of neutrinos emitted by one GRB explosion. The differential number flux of GRB background neutrinos, dF_ν/dE_ν , using the relation $dF_\nu/dE_\nu = c dn_\nu^{\text{ob}}/dE_\nu$,

$$\begin{aligned} \frac{dF_\nu}{dE_\nu d\Omega} &= \frac{c}{4\pi H_0} \int_{z_{\min}}^{z_{\max}} dz R_{GRB}(z) \frac{dN_\nu((1+z)E_\nu)}{dE'_\nu} \\ &\times \frac{1}{\sqrt{(1+\Omega_m z)(1+z)^2 - \Omega_\Lambda(2z+z^2)}}, \end{aligned} \quad (15)$$

where we assume $z_{\min} = 0$, and $z_{\max} = 7$ or $z_{\max} = 20$. This is because the high redshift GRB event GRB 050904 is recently reported by Swift observation and the GRB distribution likely extends beyond $z = 6$ [41]. In addition, some GRBs are expected to exist at much higher redshifts than $z = 7$. First, preliminary polarization data on the cosmic microwave background collected by WMAP indicate a high electron scattering optical depth, hinting that the first stellar objects in the universe should have formed as early as $z \sim 20$ [57]. Second, theoretical simulations of the formation of the first stars similarly conclude that these should have formed at redshifts $z \sim (15-40)$ [58]. Because there are convincing evidences that at least long GRBs are associated with the deaths of massive stars, it is conceivable that high- z GRBs ($z \gtrsim 15-20$ or even higher) exist.

III. RESULTS

A. Photomeson production efficiency

We calculate the proton cooling efficiency through photomeson production by the method explained above. The obtained results on $f_{p\gamma} \equiv t_{\text{dyn}}/t_{p\gamma}$ by using GEANT4 are shown in Fig. 1. For comparison, we also show the case where the cross section has a cutoff at 2 GeV in the proton-rest frame. In this case, we checked that our result agrees with Asano [13] within a few percent. Analytic rough approximation by Δ -resonance is also shown in Fig. 1 [10]. In this approximation we set $\sigma_{p\gamma} \approx 5 \times 10^{-28} \text{ cm}^2$, $\bar{\epsilon} \approx 0.3 \text{ GeV}$, $\Delta\bar{\epsilon} \approx 0.3 \text{ GeV}$, and $\kappa_p \approx 0.2$ in the Eq. (6). At $\gamma_p \lesssim 10^7 \text{ GeV}$, Δ -resonance is a good approximation and the break energy is determined by $\epsilon_p^b \epsilon^b \sim 0.3 \text{ GeV}^2$. Protons below the break energy mainly produce pions with photons whose energies are above the break energy, so it leads to $f_\pi \propto \epsilon_p^{\beta-1}$. On the other hand, protons above the break energy mainly interact with harder photons, which leads to $f_\pi \propto \epsilon_p^{\alpha-1}$. The photomeson production efficiency obtained by GEANT4 is larger than other two cases which have the cutoff and monotonically increasing in the high energy region of the order of $\gamma_p \gtrsim 10^7 \text{ GeV}$. This is because $\kappa_p \approx 0.5\text{--}0.7$ rather than $\kappa_p \approx 0.2$ at Δ -resonance are satisfied and multipion production occurs in this region.

In this paper we adopt three parameter sets for GRB isotropic energy, photon break energy, and photon spectral indices. That is, case A: $E_\gamma^{\text{iso}} = 2 \times 10^{51} \text{ ergs}$, $\epsilon^b = 1 \text{ keV}$, and $\alpha = 1, \beta = 2.2$; case B: $E_\gamma^{\text{iso}} = 2 \times 10^{52} \text{ ergs}$, $\epsilon^b = 3 \text{ keV}$, and $\alpha = 1, \beta = 2.2$; case C: $E_\gamma^{\text{iso}} = 2 \times 10^{53} \text{ ergs}$, $\epsilon^b = 6 \text{ keV}$, and $\alpha = 0.5, \beta = 1.5$. Figure 2 shows the proton cooling efficiencies for each case. Case A and case B have the fiducial spectral

FIG. 1. Proton cooling efficiencies, $f_{p\gamma}$, for $r = 2 \times 10^{13} \text{ cm}$ and $E_\gamma^{\text{iso}} = 2 \times 10^{51} \text{ ergs}$, by GEANT4 (solid line). For comparison, we also show the case with cross section having a cutoff at 2 GeV (dashed line) and rough analytic approximation (dotted line).

FIG. 2. Proton cooling efficiencies, $f_{p\gamma}$; case A for $r = 2 \times 10^{13} \text{ cm}$ and $E_\gamma^{\text{iso}} = 2 \times 10^{51} \text{ ergs}$ (solid line), case B for $r = 5.4 \times 10^{14} \text{ cm}$ and $E_\gamma^{\text{iso}} = 2 \times 10^{52} \text{ ergs}$ (dotted line), case C for $r = 2 \times 10^{13} \text{ cm}$ and $E_\gamma^{\text{iso}} = 2 \times 10^{53} \text{ ergs}$ (dashed line). Each shell width is given by $l = r/\Gamma$.

indices of GRB photons, while case C has a rather flatter photon spectrum. In addition, case C corresponds to the case where a more energetic burst will be observed.

Figure 3–6 show various cooling time scales and acceleration time scale. Proton's maximum energy is determined by Eq. (5). Note that most of protons will be depleted in the case optically thick to photomeson production, even if a fraction of protons are accelerated up to the maximal energy indicated by the Eq. (5). For example, Figs. 3 and 4 correspond to such cases. Only in the optically thin case, a significant fraction of protons with the maximum energy can escape from the source. In these figures, for comparison, we also show η in the Eq. (3) as a parameter having the range of 1–10 (hatched lines). Figure 3 shows the case where the photohadronic cooling

FIG. 3. Various cooling time scales and acceleration time scales for case A, $r = 2 \times 10^{13} \text{ cm}$, and $\epsilon_B = 0.1$. The hatched lines show an uncertainty of the acceleration time, which corresponds to $\eta = 1 - 10$.

FIG. 4. Various cooling time scales and acceleration time scales for case A, $r = 2 \times 10^{13}$ cm, and $\epsilon_B = 1$. The hatched lines show an uncertainty of the acceleration time, which corresponds to $\eta = 1 - 10$.

is crucial for determining the maximum energy. Multiplicity and inelasticity will be important because the contribution of photohadronic cooling is comparable to synchrotron cooling if cross section has the cutoff at 2 GeV, or smaller than synchrotron cooling in the case of analytic Δ -resonance approximation. At inner radii, photon density is large, so photohadronic process can be important unless ϵ_B is enough large for synchrotron cooling to be a dominant process. When the proton's maximum energy is determined by the photohadronic process, a significant fraction of protons with the very high energy cannot escape from the accelerating site in many cases of GRB parameters. It is only possible within the limited range of radii or for the case of the moderately smaller radiation energy than our cases. In many cases of possible parameter sets for GRBs, the synchrotron cooling is the most dominant process to determine the maximum energy and such a case is demonstrated by Figs. 4 and 5. At outer

FIG. 5. The same as Fig. 3. But a result for case B, $r = 5.4 \times 10^{14}$ cm, and $\epsilon_B = 1$.

radii, the dynamical time scale will be more and more important due to decreasing of photon energy density and magnetic energy density. Figure 6 corresponds to such a case and the maximum energy of proton is restricted by t_{ad} . In our cases, significant acceleration of protons is possible only at larger radii, $r \gtrsim 10^{14}$ cm. This result is consistent with Asano [13]. Smaller E_γ^{iso} and larger r are favorable to generate UHECRs. Figures 5 and 6 demonstrate such cases where sources are optically thin to photomeson production and the production of UHECRs is possible. The effects of multiplicity and high-inelasticity appear in the very high energy region and enhances photohadronic cooling of protons. However, these effects affect cooling time scale only for the cases of inner collision radii and smaller magnetic fields, $\epsilon_B = 0.1$. In the next subsection, we will see these effects can become important only for limited cases.

B. Neutrino spectrum and flux

We can get the spectrum of pions from photomeson production efficiencies calculated by GEANT4. From pion obtained spectra we can also calculate neutrino spectra following from the method explained in Secs. IID and IIE. Figure 7 shows spectra of $\nu_\mu + \bar{\nu}_\mu$ as one of our results for $r = 2 \times 10^{13}$ cm, $\Gamma = 100$, and $\Gamma = 300$. The high energy break is mainly determined by t_{syn}/t_π . Hence the high energy break changes satisfying $\epsilon_\nu^s \propto \epsilon_B^{1/2}$ (see Fig. 7). Note, from the Eq. (1), different values of Γ give the similar neutrino spectra for the same E_γ^{iso} and r as long as $l = r/\Gamma$ is held.

Figures 8–10 show spectra from single-pion, double-pion, and multipion production origins. As seen in Figs. 8 and 9, for the case of $\alpha = 1$ and $\beta = 2.2$ that is typical for GRB, the effects of double- and multipion are negligible or comparable to that of single-pion, whose contribution can be well described by Δ -resonance approximation. Protons of energy $\epsilon_p \lesssim 10^5$ GeV can interact only with the steep part of the photon spectrum above the

FIG. 7. Neutrino spectra in the comoving frame with ϵ_B changing for $r = 2 \times 10^{13}$ cm. The upper lines are for $\Gamma = 100$ and $E_{\gamma}^{\text{iso}} = 2 \times 10^{52}$ ergs. The lower lines are for $\Gamma = 300$ and $E_{\gamma}^{\text{iso}} = 2 \times 10^{51}$ ergs. Three cases are shown, $\epsilon_B = 0.1$ (solid line), $\epsilon_B = 1$ (dashed line), $\epsilon_B = 10$ (dotted line).

break, $dn/d\epsilon \propto \epsilon^{-2.2}$. Hence the contribution of nonresonance, $\epsilon_p \gg 0.16$ GeV, is negligible. Protons with the energy $\epsilon_p \approx 10^5$ GeV can interact with the flatter part of the photon spectrum below the break, $dn/d\epsilon \propto \epsilon^{-1}$. In this case, the contribution of double and multipion production can be important because the flatter part of photon spectrum cover significant energy range. Such contribution can be crucial at the very high energy range, $\epsilon_p \approx 10^7$ GeV. At inner radii the contributions of double and multipion are negligible or comparable (see Fig. 8). Even when it is comparable, such a region is above the high energy break. Because the nonthermal proton's maximum energy is

FIG. 8. Muon-neutrino ($\nu_\mu + \bar{\nu}_\mu$) spectra in the comoving frame. Muon-neutrinos are produced by the decay of pion and muon which origins are single- or double- or multipion photo-meson production. Each case is shown. A result for $r = 2 \times 10^{13}$ cm on case A. ϵ_B is set to 1.

FIG. 9. The same as Fig. 8. But a result for $r = 5.4 \times 10^{14}$ cm on case B. ϵ_B is set to 1.

around $(10^8 - 10^{8.5})$ GeV, there are only a few very high energy protons which can produce multipions. At outer radii these contributions are comparable to or larger than single-pion fraction by a factor of $\sim (2-3)$ (see Fig. 9). However, in most of the region where multipion production dominates, the resulting neutrino spectra are suppressed by synchrotron and adiabatic cooling processes because such a region belongs to the high energy region above around the high energy break. For the case of $\alpha = 0.5$ and $\beta = 1.5$, which is the flatter photon spectrum, the multipion production has the significant effect for neutrino spectra. In this case there are sufficient high energy photons, which can interact with very high energy protons, $\epsilon_p \approx 10^7$ GeV. Figure 10 demonstrates one of such cases. In this case the contribution of multipion origin dominates single-pion origin by 1 order of magnitude even around the high energy break. Note that in the very high energy region, not only inelasticity but also multiplicity are also high. As a result,

FIG. 10. The same as Fig. 8. But a result for $r = 1.8 \times 10^{14}$ cm on case C. ϵ_B is set to 0.1.

HIGH ENERGY NEUTRINO EMISSION AND NEUTRINO ...

the average pion's energy which can be estimated by the parent proton's energy multiplied by inelasticity and divided by multiplicity cannot be so large [23].

The difference between neutrino spectra from pion decay and from muon decay is explained as follows. Neutrinos from muons dominate those emitted directly from pions in the low energy region. When a pion decays as $\pi^\pm \rightarrow \mu^\pm + \nu_\mu(\bar{\nu}_\mu)$, the energy fraction a muon obtains is typically $\sim m_\mu/m_\pi \sim 0.76$. Hence a direct neutrino from $\pi^\pm$ has a fraction of ~ 0.24 . When a muon decays as $\mu^\pm \rightarrow e^\pm + \nu_e(\bar{\nu}_e) + \nu_\mu + \bar{\nu}_\mu$, each of three species will carry similar energy. But a neutrino from $\mu^\pm$ has a smaller energy fraction than a direct neutrino from $\pi^\pm$, since muon has the longer life time than pion so that it is subject to synchrotron cooling. Figure 11 shows neutrino spectra that occur at various collision radii with the fixed shell width. In this case photon energy density changes with $U_\gamma \propto r^{-2}$. This result is consistent with Asano [13]. Figure 12 shows neutrino spectra which occurs at various collision radii with changing the shell width holding $l \approx r/\Gamma$. In this case photon energy density changes with $U_\gamma \propto r^{-2}l^{-1} \propto \delta t^{-3}$. Here, δt is the typical variability time scale. Roughly speaking, the high energy break is determined by t_{syn}/t_π again. This implies the high energy break is proportional to $r^{1/2}$. On the other hand the low-energy break is determined by the minimum energy of pions produced from protons. The dynamical time scale, t_{dyn} is proportional to l , while $t_{p\gamma}$ and t_{syn} are proportional to r^2l , so the proton cooling efficiencies, which is expressed by $f_{p\gamma} \equiv t_{\text{dyn}}/t_{p\gamma}$ and $f_{\text{syn}} \equiv t_{\text{dyn}}/t_{\text{syn}}$, are proportional to r^{-2} independently of l [13]. So, this minimum energy will depend on only r . Both the low-energy and high energy break increase roughly proportionally to r . Figures 11 and 12 confirm these statements.

FIG. 11. Muon-neutrino ($\nu_\mu + \bar{\nu}_\mu$) spectra in the comoving frame for various collision radii on case A. The subshell width is $l = 6.7 \times 10^{10}$ cm. ϵ_B is set to 1.

PHYSICAL REVIEW D **73**, 063002 (2006)

FIG. 12. Muon-neutrino ($\nu_\mu + \bar{\nu}_\mu$) spectra in the comoving frame for various collision radii on case A. The subshell width is given by $l = r/\Gamma$. ϵ_B is set to 1.

To get the total neutrino spectrum of a single burst with a collision radius r and a subshell width l simply, we only have to multiply the number of collisions N . However, here we cumulate the neutrino spectra over various internal collision radii, assuming each collision emits similar energy. It is because internal shocks may occur within some range of distances, although the distribution of collision radii is not so clear. In the internal shock model, the sequence of collisions takes place. Collisions of the subshells with the smaller separation will occur at smaller radii. The subsequent collisions will occur at larger radii. For simplicity, we assume the number of such collisions is proportional to Δ/d , where Δ is the total width of the shell. We also assume the fixed subshell width through one burst. We may need to take into account the spreading of subshells since internal shock radii are roughly comparable to the spreading radii of subshells [4]. Even so, it does not affect the resulting spectra so much because photon density becomes much smaller at larger radii. To improve our calculation, we will need a detailed calculation on the internal shock model [25,26], which is beyond the scope of this paper. We adopt three parameter sets in this study. That is, set A: $E_\gamma^{\text{iso}} = 2 \times 10^{51}$ ergs, $\epsilon^b = 1$ keV, $\alpha = 1$, $\beta = 2.2$, and $r = (10^{13} - 8.1 \times 10^{14})$ cm, and $l = 6.7 \times 10^{10}$ cm; set B: $E_\gamma^{\text{iso}} = 2 \times 10^{52}$ ergs, $\epsilon^b = 3$ keV, $\alpha = 1$, $\beta = 2.2$, $r = (2.7 \times 10^{14} - 7.3 \times 10^{15})$ cm, and $l = 1.8 \times 10^{12}$ cm; set C: $E_\gamma^{\text{iso}} = 2 \times 10^{53}$ ergs, $\epsilon^b = 6$ keV, $\alpha = 0.5$, $\beta = 1.5$, $r = (10^{13} - 8.1 \times 10^{14})$ cm, and $l = 6.7 \times 10^{10}$ cm. Set A demonstrates internal shocks begin at somewhat smaller radii, $r \sim 10^{13}$ cm. In this set, the typical variability time scale is $\delta t \sim 30$ ms and if $N = 200$, the typical jet angle is $\theta_j \sim 0.1$ rad. Set B demonstrates internal shocks begin at $r \sim 10^{14}$ cm. The typical variability time of this set is $\delta t \sim 0.3$ s and if $N = 20$, the typical jet angle is $\theta_j \sim 0.1$ rad. Set C is a very

energetic case which has the flatter photon spectrum. Three sets are shown in Figs. 13 and 14. To evaluate observed flux from one burst, we set a source at $z = 1$. Obtained neutrino flux of set A and set B are comparable with Guetta *et al.* [12]. However, such levels of neutrino flux are hardly detected by km^3 detector such as IceCube. Only the most powerful bursts or nearby sources can give a realistic chance for detection of ν_μ [11]. In our sets, only set C has the prospect for detection by IceCube. To see this, here we estimate neutrino events in IceCube. We use the following fitting formula of the probability of detecting muon neutrinos [59,60].

$$P(E_\nu) = 7 \times 10^{-5} \left(\frac{E_\nu}{10^{4.5} \text{ GeV}} \right)^\beta, \quad (16)$$

where $\beta = 1.35$ for $E_\nu < 10^{4.5} \text{ GeV}$, while $\beta = 0.55$ for $E_\nu > 10^{4.5} \text{ GeV}$. Using a geometrical detector area of $A_{\text{det}} = 1 \text{ km}^2$, the numbers of muon events from muon neutrinos a burst are given by,

$$N_\mu(>E_{\nu,3}) = A_{\text{det}} \int_{\text{TeV}} dE_\nu P(E_\nu) \frac{dN_\nu(E_\nu)}{dE_\nu dA}, \quad (17)$$

where $E_\nu = 10^3 \text{ GeV} E_{\nu,3}$. Hence, the numbers of muon neutrinos to be expected by IceCube for set C with $N = 20$ are $N_\mu = 1.9$ particles. In the case of set A with $N = 200$ and set B with $N = 20$, we obtain $N_\mu = 0.05$ and $N_\mu = 0.004$ respectively. Of course, if ϵ_{acc} is more larger, flux can be enhanced. But too large ϵ_{acc} will be suspicious. We will discuss this later.

Since we obtain neutrino spectra on various parameters above, we can calculate a diffuse neutrino background from GRBs for our specific parameter sets. The results are shown in Fig. 15–17. Figure 15 is for $z_{\text{max}} = 7$. Figures 16 and 17 are for $z_{\text{max}} = 20$. Our adopted SFR

FIG. 13. The observed muon-neutrino ($\nu_\mu + \bar{\nu}_\mu$) spectra for one GRB burst at $z = 1$. Neutrino spectra from pion and muon are shown, respectively, on set A with $N = 200$, set B with $N = 20$, set C with $N = 20$. Set A and Set B are $\epsilon_B = 1$, but Set C is $\epsilon_B = 0.1$.

FIG. 14. The observed muon-neutrino ($\nu_\mu + \bar{\nu}_\mu$) spectra for one GRB burst at $z = 1$. Neutrino spectra with various ϵ_B values are shown, respectively, on set A with $N = 200$, set B with $N = 20$, set C with $N = 20$. Set A and Set B are $\epsilon_B = 1$, but Set C is $\epsilon_B = 0.1$.

models generate similar results. When z_{max} is 20, SF3 model gives higher flux by a factor of $\sim(2-3)$ below the low-energy break than other SFR models. This is because SF3 model predicts higher SFR at high redshifts. Whether z_{max} is 7 or 20 does not affect neutrino flux up to a factor. Neutrino signals from GRBs can be marginally detected or not by IceCube in both figures. In fact, when ϵ_B is set to 1 and we use SF3 model, we can obtain $N_\mu = 14$ particles a year for $z_{\text{max}} = 7$ and $N_\mu = 17$ particles a year for $z_{\text{max}} = 20$. On the other hand, in the case of set B, we get $N_\mu = 1.2$ particles a year for $z_{\text{max}} = 7$ and $N_\mu = 1.5$ particles a year for $z_{\text{max}} = 20$.

FIG. 15. Diffuse neutrino background from GRBs for $z_{\text{max}} = 7$ on several SFR models. R-R means the case using Rowan-Robinson SFR. SF1–SF3 correspond to the models of Porciani & Madau. The left lines are for set A, while the right is for set B. For comparison, we show WB bounds (three dashed lines). The upper WB bound is for z -evolution of QSOs. The lower is for no z -evolution. $\epsilon_{\text{acc}} = 10$ and $\epsilon_B = 1$ are assumed.

FIG. 16. Diffuse neutrino background from GRBs for $z_{\max} = 20$ on several SFR models. R-R means the case using Rowan-Robinson SFR. SF1–SF3 correspond to the models of Porciani & Madau. The left lines are for set A, while the right is for set B. For comparison, we show WB bounds (three dashed lines). The upper WB bound is for z -evolution of QSOs. The lower is for no z -evolution. $\epsilon_{\text{acc}} = 10$ and $\epsilon_B = 1$ are assumed.

Our result for set A is very similar to the prediction of Waxman and Bahcall [8], although our ground is different from theirs. In this parameter set, our calculation on neutrino background from GRBs also satisfy WB bound, although this case is optically thick to photomeson production at inner radii, $r \lesssim 10^{14}$ cm. Set B expresses neutrino spectra for the case of larger collision radii than set A. In this parameter set, GRB sources are optically thin to photomeson production and can be sources of very high energy cosmic rays. It has to satisfy WB bound and this implies ϵ_{acc} can be constrained from UHECR observations

FIG. 17. Diffuse neutrino background from GRBs for $z_{\max} = 20$ with ϵ_B changing. But the large baryon-loading factor, $\epsilon_{\text{acc}} = 100$, is assumed. The upper lines are for set A, while the lower lines are for set B. All lines use the SF3 model.

if set B is fiducial for GRBs and other parameters are appropriate. If GRBs are sources of UHECRs, this set implies GRB neutrino fluxes with z -evolution, $E_\nu^2 dF_\nu / dE_\nu d\Omega \sim 10^{-8} \text{ GeV cm}^2 \text{ s}^{-1} \text{ str}^{-1}$. However, this suggests very large baryon-loading factor, $\epsilon_{\text{acc}} \sim 100$ if current GRB rate estimation is correct and our model is valid. If set A is more fiducial, similar arguments leads to even larger baryon-loading factor because UHECRs can be accelerated only at large radii. So GRBs are not main sources of UHECRs in set A. If we adopt larger isotropic energy by one order in this set with N fixed, the flux level will increase within a factor, because larger isotropic energy implies smaller θ_j (but for set B, it will increase by 1 order of magnitude, which is easily seen from the Eqs. (1), (6), and (7)). Figure 17 shows ϵ_B dependence of neutrino background. But the near extreme case, $\epsilon_{\text{acc}} = 100$ is presumed. If it is possible, neutrino will be surely observed by the detector such as IceCube. For example, when ϵ_B is set to 1 and we use SF3 model, we obtain $N_\mu = 170$ particles a year for set A with $z_{\max} = 20$ and $N_\mu = 15$ particles a year for set B with $z_{\max} = 20$. Observations of neutrino background, if detected, may give us the evidence of protons being accelerated in GRBs, support to the internal shock model of GRBs, and information about these parameters independently of X/ γ rays from GRBs.

Finally, we summarize the parameter dependence of our results as follows. The collision radii, r and the width of a subshell, l determine the photon energy density. The larger radii and width of a subshell make the resulting neutrino emissivity smaller. The low-energy break of neutrino spectrum, ϵ_ν^b , is determined by the photon break energy, but it is also roughly proportional to r . The high energy break is determined by the synchrotron (or adiabatic) cooling and satisfies $\epsilon_\nu^s \propto \epsilon_B^{1/2}$. We take $\epsilon_B = 0.1, 1, 10$ (in the case of afterglow, $\epsilon_B = 0.1$ is preferred). The high energy break is also roughly proportional to $r^2 l$. One of the most important parameters is the nonthermal baryon-loading factor, ϵ_{acc} . We set ϵ_{acc} to 10 except Fig. 17 and the larger ϵ_{acc} can raise the flux level of neutrino, although too large ϵ_{acc} is not plausible. We take $E_{\gamma, \text{tot}}^{\text{iso}} \sim (10^{52} - 10^{54})$ ergs, and more energetic bursts can produce more neutrinos when other parameters are fixed.

IV. SUMMARY AND DISCUSSION

In this paper we calculate proton's photomeson cooling efficiency and resulting neutrino spectra from GRBs quantitatively. We are able to include pion-multiplicity and proton-inelasticity by executing GEANT4. These effects of multipion production and high-inelasticity in the high energy region enhance the proton cooling efficiency in this region, so they help prevent protons from accelerating up to the ultra-high energy region in several cases. But in many cases, the synchrotron loss time scale and the dynamical time scale determine proton's maximum energy.

Furthermore, resulting neutrino spectra are not so sensitive to the nonthermal proton's maximum energy except the very high energy region above the high energy break.

In our cases GRBs are optically thick to photomeson production at $r \lesssim 10^{14}$ cm, while at $r \gtrsim 10^{14}$ cm GRBs are optically thin to it, so the production of UHECRs is possible at larger radii. This result is consistent with Asano [13]. Using the obtained proton cooling efficiency, we can calculate neutrino spectra. The effects from multipion production on resulting spectra are also calculated. We show that the contribution of multipion is almost negligible at inner radii but can be larger than that of single-pion at outer radii by a factor. In addition, the contribution of multipion production is somewhat sensitive to the proton's maximum energy, which would be actually difficult to determine precisely due to uncertainty of η . But such a contribution can be significant for the flatter photon spectrum, even though mesons lose their energy through these cooling process. Radiative cooling of pions and muons plays a crucial role in resulting spectra. Neutrino spectra are suppressed above the high energy break energy. If the magnetic field is strong, such suppression becomes large and vice versa, if the magnetic field is weak, such suppression becomes weak. The observations of neutrino has the possibility that gives us some information about such a parameter of GRBs independently of gamma-ray observation. However, as shown in Dermer and Atoyan [11], only the most powerful bursts, which are brighter than $\sim 10^{53}$ ergs or bursts at $z \lesssim 0.1$, produce detectable neutrino bursts with a km^3 detector such as IceCube. Set C of our parameter sets would be one of such detectable cases, but only a few neutrinos are expected even for the brightest bursts. For one neutrino burst, we adopt $\Gamma = 300$ and consider only the on-axis observations. If we observe at off-axis, we will observe lower energy neutrinos.

A diffuse neutrino background is also calculated in this paper. In our specific parameter sets, neutrino background observations by IceCube can expect a few or a few tens order of neutrinos per year, although it is important which parameter set is fiducial. Extrapolation of SFR to high redshifts may not be valid. Even so, our results would not be so much affected as we have seen above. In addition, GRBs may trace not SFR, but metallicity. In the collapsar model, the presence of a strong stellar wind (a consequence of high metallicity) would hinder the production of a GRB, therefore metal-poor hosts would be favored sites [49]. There remains large uncertainty at low metallicity at present, and as more bursts are followed up and their environments are better studied by Swift, this correlation will be testable. However, our results will not be changed so much even when we can take into account this.

Throughout this paper, we set N to the range of $\sim (10-100)$. If we change N , a neutrino signal from one burst will change with N . On the other hand, when we calculate a neutrino background, the results are not

changed unless we fix E_{γ}^{iso} . This is because θ_j varies according to the change of N since we fix E_{γ}^{iso} and $E_{\gamma, \text{tot}}$. However, the results will be changed when we fix θ_j and $E_{\gamma, \text{tot}}$. For example, on set B, we will get the lower flux level by 1 order of magnitude if we adopt $N = 200$ fixing $E_{\gamma, \text{tot}}$, θ_j , and ϵ_{acc} . This is easily seen from the $E_{\gamma, \text{tot}}^{\text{iso}} = f_b^{-1} E_{\gamma, \text{tot}}$ and the Eqs. (1), (6), and (7). When we fix $E_{\gamma, \text{tot}}$, θ_j , and ϵ_{acc} , more shells mean lower photon energy density. For set B, which is the case optically thin to photomeson production, it leads to decrease $dn_{\pi}/d\epsilon_{\pi}$ roughly by 2 orders of magnitude. Hence, the total neutrino spectra will be lower by 1 order of magnitude. If we fix θ_j , our results in which N is set to ~ 10 , would give the reasonable flux level in the optimistic case.

In our parameter sets both one burst emission and a diffuse neutrino background give the neutrino flux we can barely observe by IceCube. To raise flux, GRBs require the larger nonthermal baryon-loading factor, ϵ_{acc} , which is difficult to estimate from microphysics at present. However, there are some clues and assuming too large ϵ_{acc} will not be plausible. First, as seen in Sec. III B, UHECRs observations can give the upper limit to ϵ_{acc} . Furthermore, the large baryon-loading factor suggests a significant contribution of the accelerated protons in the observed hard radiation through secondaries produced in photomeson production. Such emission is expected to be observed in the multi-GeV energy range by electromagnetic cascades [10,24,61]. If the flux level of multi-GeV emission is comparable to the neutrino flux obtained in this paper, the flux level will be below that of X/ γ emission and the EGRET limit. But assumed photon spectra will be modified by the radiation from secondaries. In addition, such high energy emission may be detected by the near future GLAST observation [62]. Although it is important both to compare X/ γ emission with such multi-GeV emission and to investigate whether GLAST can detect such multi-GeV emission or not, a detailed calculation for this purpose is needed and it is beyond the scope of this paper. If such a calculation is done, GLAST observation in the near future has the possibility to give more information about ϵ_{acc} . This will be the second clue about ϵ_{acc} . Third, ϵ_{acc} will be constrained by the GRB total explosion energy, which is still unknown. The large baryon-loading factor leads to the large explosion energy. For example, if the true total explosion energy is $\lesssim 10^{53}$ ergs, this suggests $\epsilon_{\text{acc}} \lesssim 100$.

On the other hand, GRBs associated with supernovae may imply the isotropic kinetic energy, $E_{\text{kin}}^{\text{iso}} \gtrsim 10^{52}$ ergs, which is larger than usual supernovae by 1 order of magnitude [63]. This leads to a collapsar model as a failed supernova in the sense that a core collapse event failed to form a neutron star and instead produced a black hole [49]. Here, we assume the internal shock scenario is correct and a collapsar model is valid. If the true total explosion energy of a collapsar is assumed to be $\lesssim 10^{53}$ ergs, neutrino

spectra will be limited by $f_{cl}\epsilon_{acc} \lesssim 10^{-1}$ because f_{cl} is constrained by $f_{cl} \lesssim 10^{-3}$ from current GRB rate estimations. So if observed neutrino spectra is higher than these values, the collapsar model cannot explain the spectra alone. On the other hand, the supernova model predicts higher neutrino flux by a pulsar wind [11,64]. If the observed neutrino flux is higher than expected in the collapsar model, the supernova model might be likely to exist.

If IceCube can detect neutrinos and confirms they have the expected level of neutrino flux by our calculation, this will be one of the evidences that a significant fraction of protons can be accelerated and our employed internal shock model is valid. Of course, to estimate neutrino background more precisely and make our discussion justified, we have to choose the most fiducial parameters for GRBs. The results depend on photon density, and the contribution from a fraction of bursts with large photon density might be large. So, we should take into account the respective distributions of parameters to execute the most refined calculation. Unfortunately, many parameters have large uncertainty at present. For this reason, we calculate for a wide range of these parameters in this paper. The signature of GRBs may depend on z . For example, the total isotropic energy of a GRB and photon spectral indices may depend on z . More and more observations in the near future and more refined theoretical models will allow our results to be improved.

So far, we have not taken account of neutrino oscillations. Since we have considered many decaying modes, the production ratio of high energy muon and electron neutrinos is not 2:1 exactly. However, the neutrinos will be almost equally distributed among flavors as a result of vacuum neutrino oscillations [10]. So there may be a possibility that tau neutrinos are detected through double bang events [65].

In summary, we obtain the neutrino spectrum from GRBs quantitatively by using GEANT4 simulation kit. We show that photomeson cooling process can constrain the proton's maximum energy and the effects of multipion production and high-inelasticity can enhance the cooling

efficiency. Furthermore, these effects affect the resulting neutrino spectra slightly and can be significant for the flatter photon spectrum. We quantitatively checked radiative cooling of pion and muon play a crucial role, which is controlled by ϵ_B . We also confirmed that UHECRs can be accelerated at $r \gtrsim 10^{14}$ cm. We have calculated not only neutrino spectra from one burst but also the GRB diffuse neutrino background using several SFR models. We have found our specific parameter sets give neutrino spectra comparable with the prediction of Waxman and Bahcall [10] without supposing the very large nonthermal baryon-loading factor, which is necessary for the assumption that GRBs are main sources of UHECRs. We have also discussed influences on neutrino spectra by changing parameters. Such a study is important since there are many parameters. If neutrino signals are detected by AMANDA, ANTARES, NESTOR, or IceCube, it will be one of the evidences that protons can be accelerated to very high energy in GRBs and the internal shock model of GRBs are plausible. Furthermore, such neutrino observations in the near future may give us some information about the nonthermal baryon-loading factor and the inner engine of GRBs.

ACKNOWLEDGMENTS

We are very grateful to K. Asano for many useful comments and advises for calculation. We also thank the referee and K. Ioka for a lot of profitable suggestions. K. M. is grateful to K. Miwa and G. Normann for using GEANT4 simulation. We also thank M. Mori, H. Kurashige, T. Hyodo, and D. Wright for GEANT4.
