ABSTRACTS

We examined the role of the intrapharyngeal pressure to the laryngeal adjustment during the production of voiceless plosive [k] in the running speech. By videofiberscopy and manometory, we analyzed the relationship between the degree of the glottal opening and the intrapharyngeal pressure.

In normal subjects, spindle shaped glottal opening was observed and the intrapharyngeal pressure was increased to about 4.7 cm H₂O.

In patients with velopharyngeal insufficiency after hemiglossectomy or pharyngeal resection, glottal opening was not observed and intrapharyngeal pressure was lower than that of normal subjects.

The same result was obtained, when artificial velopharyngeal insufficiency was produced.

In a tracheoesophageal shunt speaker after total laryngectomy, neoglottal opening was observed.

These results suggested that spindle shaped glottal opening during the articulation of voiceless plosive [k] in the running speech was caused passively by increased intrapharyngeal pressure.

INTRODUCTION

It is known that the glottal opening and stop of vocal cord vibration is observed during the production of voiceless consonants, and which has been believed to be regulated by the intrinsic laryngeal muscles.

On the contrary, we reported the possibility that intrapharyngeal pressure might cause the glottal opening and stop of vocal cord vibration during the production of plosive voiceless consonant [k] in the running speech¹).

Glottal opening means, spindle shaped opening of membranous vocal cords, but not the full abduction of vocal cord. (Figure 1)

Kazuhiko Shoji (庄司和彦) : Associate Professor, Department of Otorhinolaryngology, Kyoto University
Iwao Honjo (本庄 和) : Professor, Department of Otorhinolaryngology, Kyoto University
As mentioned above, glottal opening and stop of vocal cord vibration may be passive phenomenon induced by the increased intrapharyngeal pressure in the running speech.

Therefore we tried to elucidate the role of intrapharyngeal pressure to the laryngeal adjustment during the production of voiceless consonant [k].

**METHOD**

We examined the influence of the degree of velopharyngeal closure on the condition of vocal cord and the intrapharyngeal pressure by the following methods (Figure 2).

1: We examined the condition of vocal cord and the intrapharyngeal pressure of 12 normal subjects (7 males, 5 females) and those of 4 patients of post hemiglossectomy or partial pharyngectomy with velopharyngeal insufficiency. Table 1 shows the list of patients with velopharyngeal insufficiency.

2: In 5 normal subjects, before and after velopharyngeal insufficiency artificially produced by retracting soft palate, the condition of vocal cord and the intrapharyngeal pressure were examined.

3: In a tracheoesophageal shunt speaker after total laryngectomy, the condition of neoglottis and the intrapharyngeal pressure was examined.

The subjects of analysis were two sets of consonant [k] in the Japanese running speech[yabunonakakara usagiga pyokonto detekimashita].

The underlined former [k] was indicated as [k1], the latter [k] as [k2]. Intrapharyngeal pressure was measured by the pressure transducer 4fr. in diameter inserted transnasally into the mesopharynx. Pressure signal was recorded on a videotape simultaneous with the image of larynx (30 frames/sec). We analyzed the relation between the degree of the glottal opening and the intrapharyngeal pressure frame by frame.

In the analysis of the condition of vocal cord, (+ +) means both the spindle shape opening of vocal cord and stop of vocal vibration was observed clearly, (−) means both of them were not observed, (+) shows the median condition between (+ +) and (−).
RESULTS

1: Table 2 shows the condition of vocal cord during the production [k] in the running speech.

In all normal subjects, spindle shaped glottal opening was observed in both [k1] and [k2]. In the patients of post hemiglossectomy or partial pharyngectomy with velopharyngeal insufficiency, glottal opening was not observed clearly (Figure 3).

The mean intrapharyngeal pressure of both [k1] and [k2] in normal subjects was 4.7 cm H₂O. That of the latter group was 3.3 cm H₂O at [k1] and 2.3 cm H₂O at [k2], which was significantly lower than that of normal subjects (Figure 4).

2: The condition of vocal cord before and after artificial velopharyngeal insufficiency, are shown in table 3.

The spindle shaped opening of vocal cord was not observed at all with artificial velopharyngeal insufficiency. Figure 5 shows one of the records of the vocal cord and the intrapharyngeal pressure before and after artificial velopharyngeal insufficiency.

Fig. 3. Conditions of vocal cord during production [k].
A: normal subject; glottal opening of membranous vocal cords was observed (2~3)
B: velopharyngeal insufficient patient; glottal opening was not observed
After artificial velopharyngeal insufficiency, the mean pressure of \([k1]\) decreased from 4.7 cm H\(_2\)O to 2.3 cm H\(_2\)O and that of \([k2]\) decreased from 4.6 cm H\(_2\)O to 2.6 cm H\(_2\)O (Figure 6).

3: In a tracheoesophageal shunt speaker, neoglottic opening and stop of mucosal vibration was observed together with the increased intrapharyngeal pressure during the production \([k]\).

Figure 7 shows the neoglottis and the intrapharyngeal pressure signal.

**DISCUSSION**

The degree of glottal opening varies according to the type of consonants.
Hirose et al.\(^2\) demonstrated by the electromyographic study of intralaryngeal muscles that glottal opening and the stop of vocal cord vibration during the phonation of voiceless consonants were controlled by the reciprocal activity of abductor muscle and adductor muscles.

In short, for the voiceless sound, there is activation of posterior cricoarytenoid muscle, the abductor, accompanied by suppression of interarytenoid muscle, one of the adductors. These muscle activities are applied certainly during the phonation of...
voiceless [k] at the head of a single syllable. In the running speech, however, vocal
cord did not abduct and spindle shaped glottal opening was observed between
the membranous vocal cords by our careful fiberoptic examination.

These phenomena of the vocal cord in running speech made us think that there
should be another mechanism to control laryngeal adjustment.

By the study of speech characteristics of aged persons, we mentioned
intrapharyngeal pressure was taken into consideration for laryngeal adjustment in
We tried to elucidate the role of intrapharyngeal pressure to the laryngeal adjustment during the production of voiceless [k] by three methods in this study.

Glottal opening was not observed clearly and the intrapharyngeal pressure was much lower in the patients of post hemiglossectomy or partial pharyngectomy with velopharyngeal insufficiency than that in normal subjects. When velopharyngeal insufficiency was produced by retracting the soft palate in normal subjects, glottal opening was not observed and intrapharyngeal pressure was reduced remarkably during the production [k]. The velopharyngeal insufficiency is considered to be the cause of the lower intrapharyngeal pressure which may cause poor glottal opening. Since neoglottal opening and stop of mucosal vibration was observed with the increasing of intrapharyngeal pressure during the production [k] in tracheoesophageal shunt speech, it is inferred that neoglottal opening might be induced passively by the increasing intrapharyngeal pressure. Figure 8 shows the influence of intrapharyngeal pressure on the condition of vocal cord schematically during the articulation of voiceless consonant [k]. During the production of [k], the closure at the articulation point followed by increased intrapharyngeal pressure, induced the glottal opening.
and the stop of mucosal vibration. In velopharyngeal insufficiency, however, intrapharyngeal pressure is low and the vibration of mucosal wave dose not stop. In short, the vocal cord vibration is considered to be controlled passively by velopharyngeal closure at the articulation point during the production of voiceless plosive [k] in the running speech.
